In experiments with artificial membranes composed of phosphatidylethanolamine, phosphatidylcholine, and phosphatidylserine in a 2:2:1 ratio, defensins NP-1 (rabbit) and HNP-1 (human) formed voltage-dependent channels, requiring negative potential on the membrane side opposite to where defensins were applied (Kagan et al. 1990). Evidently, insertion of defensin molecules

into the membrane is aided when transmembrane electrical forces attract the positively charged defensin molecule. Unlike melittin, a bee-venom peptide that indiscriminately rendered vesicles composed of neutral or anionic phospholipids permeable, defensins were much more active against vesicles containing negatively charged phospholipids (Fujii et al. 1993).

In general, the membranolytic activity of defensins on phospholipid vesicles was diminished by increased salt concentrations, supporting the importance of electrostatic interactions between the cationic (positively charged) defensins and the anionic (negatively charged) head groups of membrane phospholipids. In other experiments, large unilamellar vesicles composed of palmitoyloleoylphosphatidylglycerol (POPG), a negatively charged phospholipid) were permeabilized by human defensin HNP-2 and adding neutral phospholipids to the lipid mix inhibited both defensin binding and permeabilization (Wimley et al. 1994). The importance of anionic phospholipids in defensin–membrane interactions was also shown by calorimetric measurements of phase transitions in membranes (Lohner et al. 1997). In the aggregate, these studies show that both externally applied and local electric fields influence the ability of defensin molecules to insert into a target membrane.

It is less certain what happens once the defensin molecules are in the membrane. The observed leakage of dye markers from liposomes implies the formation of stable or transient transmembrane pores. (We use the term 'pore' to refer to any type of ion or water-permeable structure or lesion within the membrane.) For some defensins, the release of internal markers from each vesicle appeared to occur in an all-or-none fashion (Wimley et al. 1994), suggesting the formation of stable pores with a diameter estimated at 2.5 nm by using markers with different sizes. The authors proposed a model of a defensin pore – a hexamer of dimers that could generate an opening of the observed size. However, stable pore formation is not the only mechanism of defensin interaction with membranes. The more cationic rabbit defensins induced a partial release of markers from individual vesicles, indicating that the pores formed were not stable. Possibly, electrostatic repulsion between the highly cationic rabbit defensin molecules destabilizes the pores.

MICROBIAL RESISTANCE

Specific mechanisms that confer increased bacterial resistance to defensins have been identified by insertional mutagenesis. Disruption of the two-component transcriptional regulator phoP-phoQ increased the sensitivity of *Salmonella* spp. to defensins and other cationic peptides (Groisman et al. 1989, 1992; Miller et al. 1990; Miller 1991). The phoP-phoQ directly regulates multiple genes involved in resistance to cationic peptides and also exerts some of its activity by modulating a second two-component regulator, PmrA-PmrB. The function of the downstream genes includes covalent modification of LPSs that decreases their affinity for cationic peptides (Guo et al. 1998) and expression of membrane proteases that degrade cationic peptides (Guina et al. 2000). In *Neisseria gonorrhoeae*, a bacterium that is naturally resistant to defensins (Qu et al. 1996), the energy-dependent efflux system *mtr* increases the resistance to protegrins, potently antimicrobial β-hairpin peptides originally isolated from pig neutrophils (Shafer et al. 1998). In staphylococci, the disruption of either of two genes, *dlt* or *MprF*, increased sensitivity to defensins (Peschel et al. 1999, 2001). The *dlt* gene is required for covalent modification of cell wall teichoic acid by alanine, and *MprF* is needed for covalent modification of membrane phosphatidylglycerol with l-lysine. By decreasing the negative charge of the cell wall and bacterial membrane, respectively, these mutations diminish their attraction for the cationic defensins. Homologs of these resistance genes exist in many bacterial species, indicating that similar mechanisms may be widespread.

OTHER ACTIVITIES

Various defensins have chemotactic activity for monocytes, T lymphocytes, and dendritic cells (Territo et al. 1989; Chertov et al. 1996; Yang et al. 1999, 2000). Human β defensins-1 and -2 (HBD-2) attract memory T cells and immature dendritic cells, apparently by binding to the chemokine receptor CCR6 (Yang et al. 1999). Although the physiological significance of this interaction is uncertain, the high concentrations of HBD-2 in inflamed skin might allow this defensin to compete effectively with the natural chemokine ligand (variously named CCL20, LARC, or MIP-3α) despite the latter's higher affinity for the CCR6 receptor. Recent structural analysis of CCL20 pointed out remarkable similarities to HBD-2 in the putative receptor-binding region of CCL20. The role of this region in the chemotactic activity of HBD-2 needs to be confirmed by mutating the amino acid residues suspected in its interaction with CCR6. Human neutrophil defensins HNP-1–3 were reported to be chemotactic for monocytes (Territo et al. 1989), naive T cells, and immature dendritic cells (Yang et al. 2000) but a specific receptor remains to be identified. Murine β-defensin-2 acted like an in vivo adjuvant for anti-tumor immunization, and induced dendritic cell maturation by activating Toll-like receptor-4 (TLR4), leading to a type 1 polarized adaptive response in vivo.

Certain defensins, especially rabbit NP-3A, can oppose the action of adrenocorticotropic hormone (ACTH) by binding to ACTH receptor without activating it (Tominaga et al. 1990). NP-3A was called Corticostatin-1 (CS-1) by some investigators (Zhu et al. 1989; Solomon et al. 1991) who failed either to recognize or to acknowledge that their sequences were identical.

By inhibiting production of cortisol (an immunosuppressive hormone) in vivo, this property might enhance the net response to infections. Tominaga et al. (1992) used an antiserum against synthetic rabbit NP-3a (CS-1 in their terminology) to examine the peptide's distribution in several rabbit tissues, including the hypothalamic–pituitary–adrenal axis. Lung and spleen had the highest levels of immunoreactivity, and relatively high levels were also detected in the pituitary, adrenal medulla, and small intestine, although not in the hypothalamus. Plasma levels of NP-3A averaged 7.8 ng/ml, and increased to 185.4 ng/ml with infection. Levels of NP-3A in the adrenal gland, small intestine, and hypothalamus also increased in rabbits with active inflammation. Although these data suggest that NP-3A (CS-1) may affect the hypothalamic–pituitary–adrenal axis in an endocrine or paracrine manner, the physiological role – if any – of corticostatic activity remains to be demonstrated.

Nanomolar concentrations of some defensins activate nifedipine-sensitive calcium channels in mammalian cells (MacLeod et al. 1991; Bateman et al. 1996). Certain mouse Paneth cell defensins (called 'cryptdins' to commemorate their presence in murine small intestinal crypts) activate chloride secretion, most probably by forming channels in the apical membrane of epithelial cells (Lencer et al. 1997; Merlin et al. 2001). This activity is limited to a subset of cryptdins, and its structural basis is not yet known. It is difficult, at present, to reconcile the multiple and varied activities of defensins with any simple receptor–ligand model.

We have recently discovered that certain α and θ defensins interact with various sugars and that this lectin-like property underlies their high-affinity binding to functionally significant glycoproteins and glycolipids. As immunoglobulins, cellular receptors, and viral envelope proteins used to promote cell entry are frequently glycosylated, this property (sugar binding) may affect many activities of defensins, especially their antiviral properties.

Defensin biosynthesis

In humans, multiple genes encoding various α and β defensins are clustered on chromosome 8p23 (Sparkes et al. 1989; Harder et al. 1997; Liu et al. 1997, 1998; Frohlich et al. 2001). Additional defensin-related genes were identified in four other clusters, so that, overall, as many as 30 transcribed defensin genes may exist in 'mice and men' (Schutte et al. 2002). It has been difficult to map the primary defensin locus in 8p23, presumably as a result of its polymorphic nature and because individuals and their chromosomes differ in the number of copies of certain defensin genes (Mars et al. 1995). α defensins are generally encoded as a tripartite pre-propeptide sequence, wherein a 90–100 amino acid precursor contains an amino terminus consisting of a 19 amino signal sequence, an anionic propiece of about 45 amino acids, and a carboxy-terminal mature cationic defensin of about 30 amino acids (Daher et al. 1988) (Figure 4). In many cases, the charges of the propiece and the mature defensin approximately balance (Michaelson et al. 1992), and this arrangement may be important for folding and/or to prevent intracellular interactions with membranes (Liu and Ganz 1995; Valore et al. 1996).

α-defensin synthesis by PMNs takes place in the bone marrow, in precursor cells called promyelocytes (Yount et al. 1995; Arnljots et al. 1998; Cowland and Borregaard 1999). Mature neutrophils in blood or inflamed tissues contain large amounts of defensin peptides, but no longer synthesize significant amounts of the peptides or their RNA. In myeloid cell lines, the defensin signal sequence is rapidly removed during synthesis. Subsequent proteolytic processing takes many hours, and is completed in maturing cytoplasmic granules (Valore and Ganz 1992). Defensin processing is a very efficient process, because only small amounts of incompletely processed intermediates are detectable in mature neutrophils (Harwig et al. 1992).

Processing the α-defensins (cryptdins) of murine intestinal Paneth cells requires a metalloprotease called matrilysin (MMP-7), because mice with homozygous disruption of the matrilysin gene fail to process Paneth cell pro-defensins past the removal of the signal sequence. In humans, processing of Paneth cell defensins takes place after secretion and involves Paneth cell trypsin (Ghosh et al. 2002). β-defensin precursors are structurally less complex than α-defensin precursors, having a signal sequence, a short or absent propiece, and a C-terminal mature defensin domain. It is not yet clear why β-defensin precursors can lack an anionic propiece and α-defensin precursors apparently must have one.

Defensin sequences and composition

Except for the conservation of their cystine framework and a few additional residues, the amino acid sequences of mature defensins are highly variable. Clusters of positively charged amino acids are characteristic of most α and β defensins but their specific distribution within the defensin molecule is inconstant (Figure 5 and see Figure 4).

STORAGE AND DELIVERY

In leukocytes and Paneth cells of the small intestine, defensins are stored in granules. These subcellular storage organelles are rich in negatively charged glycosaminoglycans (Spicer et al. 1967; Olsson 1970; Fromm et al. 1995; Hileman et al. 1998). With the exception of chicken gallinacins, these α and β defensins contain arginine as the predominant cationic amino acid. In contrast, β defensins that are secreted from epithelial cells contain similar amounts of arginine and lysine. The preferential use of arginine in defensins stored in

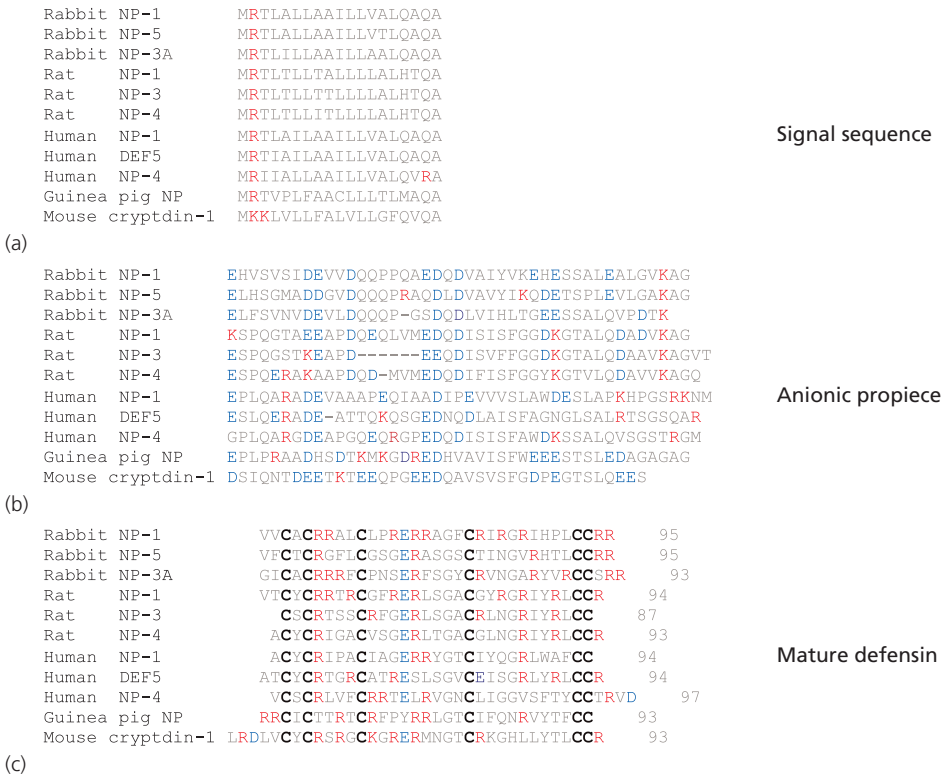

Figure 4 *Sequences of α-defensin precursors. Eleven α defensins from four species are shown. Positively charged amino acids, arginine (R) and lysine (K), are red; negatively charged residues, aspartic (D) or glutamic (E) acid, are blue; cysteine (C) is black. Note that:* **(a)** *the signal sequences are highly conserved;* **(b)** *the long propiece has a net negative charge; and* **(c)** *the mature defensin domain contains 29 (human NP-1) to 35 (mouse cryptdin-1) residues, including six conserved cysteines, and has a net positive charge.*

granules may reflect the constraints imposed by packing defensin molecules into the glycosaminoglycan matrix of granules. Alternately, synergistic interactions between defensin and myeloperoxidase, or its downstream products (e.g. HOCl), might have favored the selection of arginines over lysines. Myeloperoxidase is present in mammalian neutrophils but is absent from those of chickens and other fowl (Penniall and Spitznagel 1975; Rausch and Moore 1975).

STRUCTURE–FUNCTION CONSIDERATIONS

At present, no single mechanism explains how defensins kill bacteria, or even if the critical lethal event that defensins inflict is membrane permeabilization. In part, the present uncertainty reflects the diversity in net charge, amino acid sequence, and quaternary structure (monomers versus dimers) found among defensins. It seems likely that these differences evolved to allow defensins to recognize and target bacteria with different cell wall or membrane structures, or different patterns of metabolism or growth. Furthermore, although interactions between defensins with model membranes have been examined (Wimley et al. 1994), they may provide only a first approximation of the events that transpire in more complex biological systems. Further work in this area is needed.

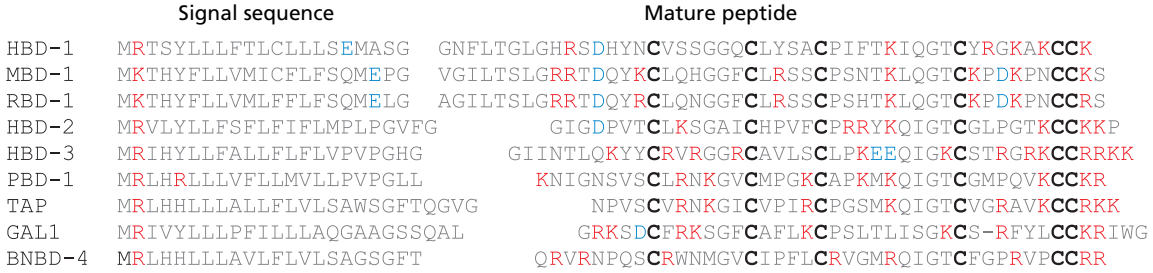

Figure 5 *Sequences of β-defensin precursors. Nine peptides from six species are shown. β-Defensin precursors are considerably shorter than α-defensin precursors, primarily as a result of the presence of a much smaller propiece. Mature β-defensin peptides are positively charged (especially so in HBD-3 or TAP – transporter associated with antigen processing), are longer than α defensins, and the spacing of their six conserved cysteines differs from that seen in α defensins.*

CATHELICIDINS

Cathelicidins are bipartite molecules with a conserved amino-terminal 'cathelin' domain containing about 100 amino acid residues (Zanetti et al. 1995, 2000). The word cathelin is an acronym for cathepsin L inhibitor, and was chosen to commemorate the domain's homology to cystatins, a family of proteins that inhibit cysteine proteases. This inference was supported by later X-ray crystallography and NMR studies (Sanchez et al. 2002a, 2002b). These studies revealed that the cathelin domain and other cystatin family members had similar backbone folds; namely an amino-terminal helix surrounded by a four-stranded β sheet. In addition, the core hydrophobic residues and disulfides of cathelin and cystatins were conserved. Although the function of the cathelin domain remains uncertain, it may protect cathelicidin precursors from premature proteolytic activation during their targeting, packaging, and storage. In many cathelicidins, the carboxy-terminal domain has both antimicrobial and LPS-binding properties. Although the antimicrobial properties of cathelicidins remain latent until the C-terminal peptide is separated from the cathelin domain by limited proteolysis (Zanetti et al. 1993), the LPS-binding properties may not require this activation step (Zarember et al. 2002).

Cathelicidins with short antimicrobial domains

Cathelin-associated antimicrobial peptides vary considerably in size and structure. The smallest are the 12-residue dodecapeptides (also called cyclic 'bactenecins') found in cattle and sheep. The peptides have similar sequences – RLCRIVVIRVCR (bovine) and RICRIIFLRVCR (sheep) – and contain a disulfide bond between their cysteine residues. Bovine indolicidin has 13 residues (ILPWKWPWWPWRR), including 5 tryptophans. Its small size and unusual composition has made it a favorite for analog design and structure–activity studies. NMR studies of indolicidin performed in a membrane-like environment composed of dodecylphosphocholine micelles revealed a well-defined, extended backbone between residues 3 and 11, with half-turns at residues Lys5 and Trp8. The peptide's central hydrophobic core, which is proline and tryptophan rich, was bracketed by positively charged side chains closer to its ends. All but one tryptophan side chain folded flat against the backbone, imparting a wedge shape to the molecule. Indolicidin's preferred location in micelles and lipid bilayers was at the membrane interface. It bound purified LPS with high affinity, and permeabilized the outer and inner membranes of *E. coli* (Falla et al. 1996). When a sufficiently electronegative potential (threshold −70 to −80 mV) was applied to the distal face of a model planar lipid bilayer, the peptide induced transmembrane currents and formed discrete channels with a conductance ranging from 0.05 to 0.15 nanosiemens (nS).

Tritrpticin (VRRFPWWWPFLRR) is a 13-residue antimicrobial peptide with a precursor that is expressed by porcine leukocytes as part of the pro-piece of a 79-residue proline and phenylalanine-rich peptide called prophenin (Harwig et al. 1995). The initial studies of tritrpticin showed activity against *Escherichia coli*, *Pseudomonas aeruginosa*, *Klebsiella pneumoniae*, *Staphyloccus epidermidis*, *Proteus mirabilis*, group D streptococci, and *Aspergillus fumigatus*. The peptide was bactericidal rather than bacteriostatic and its activity was completely inhibited by 2 mmol/l $MgCl_2$ (Lawyer et al. 1996).

In sodium dodecylsulfate micelles, tritrpticin's adjacent turns cluster its hydrophobic residues and separate them from the positively charged arginines, making the peptide amphipathic (Schibli et al. 1999). Spin-label studies showed tritrpticin near the micelle surface, with its aromatic side chains equally partitioned into the hydrophilic–hydrophobic interface and its tryptophan residues inserted. The tryptophan side chains inserted more deeply in vesicles that contained phospholipids with anionic phosphatidylglycerol head groups (Schibli et al. 2002).

Cathelicidins with β-sheet antimicrobial domains

To date, protegrins are the only cathelin-associated antimicrobial peptides with a β-sheet structure. Three protegrin peptides (PG-1,-2, and-3 were purified from porcine leukocytes, and two additional protegrins (PG-4 and-5) were identified by cloning studies. Porcine protegrins contain 16–18 amino acid residues, including four cysteines that form two intramolecular disulfides. These disulfides are essential to preserve optimal broad-spectrum antimicrobial activity in physiological saline. Although protegrins are much smaller than defensins, they show substantial sequence similarity to rabbit defensin, NP-3a. Relatively low concentrations of protegrins (<5 μg/ml) rapidly kill a very wide range of bacteria and fungi, including organisms that are resistant to conventional antibiotics. These properties, in combination with their small size and relatively simple production by direct chemical synthesis, has led to their use in mechanistic studies and as templates for pharmaceutical development (Bellm et al. 2000). Protegrins PG-1 and PG-3 have immunomodulatory properties, because both initiated the processing of pro-interleukin-1β from LPS-stimulated human monocytes, resulting in the efficient release of mature interleukin 1β (IL-1β) (Perregaux et al. 2002).

Cathelicidins with proline-rich antimicrobial domains

The cathelicidins of pigs and ruminants include several with remarkably proline-rich (40–50 percent proline!)

antimicrobial domains (Table 1), with either arginine or phenylalanine the next most abundant residue. In bovine bactenecin-7 (Bac7), most prolines are evenly spaced and separated by a single nonproline residue. Bovine Bac5 and porcine PR-39 contain several repeats of a 'PPXX' motif (i.e. two prolines followed by two nonproline residues). The initial 60 residues of prophenins 1 and 2 are repeated proline-rich decamers. Both of these prophenin isoforms were found in porcine lung surfactant preparations prepared by chloroform/methanol extraction (Wang et al. 1999) and contained, in addition to the expected components (98 percent phospholipids and 1–2 percent surfactant-associated proteins B and C), three prophenin-related molecules. These were: full-length prophenin-1; FPPPPPFRPPP FGPPRF – the carboxy-terminal octadecapeptide of prophenin-1; and a variant of prophenin-2 with an amino-terminal pyroglutamic acid extension. These components may have contributed to the antimicrobial properties of the preparation, the commercial equivalent of which (Curosurf) has been given to tens of thousands of pre-term infants with respiratory distress syndrome since its European introduction in 1992.

PR-39, a proline- and arginine-rich cathelicidin peptide found in porcine PMNs, has no known human counterpart. The peptide was initially detected as a result of its antimicrobial properties, but was subsequently reported to modulate proteoglycan production in wounds (Gallo et al. 1994), to promote leukocyte chemotaxis (Huang et al. 1997), to interact with intracellular -SH_3 proteins (Chan and Gallo 1998), and to inhibit superoxide production by PMNs (Shi et al. 1996). Expression of PR-39 and protegrin by porcine bone marrow increased substantially after experimental infection with *Salmonellas typhimurium* or in vivo administration of LPS (Wu et al. 2000). In vitro, expression of PR-39 and protegrin by cultured porcine bone marrow cells increased in response to IL-6 or all-*trans*-retinoic acid. The PR-39 and protegrin genes have upstream binding sites for IL-6 and retinoic acid, as well as potential C/EBP-binding motifs (Wu et al. 2000).

Cathelicidins with α-helical domains

Most cathelin-associated antimicrobial peptides are α helical. Typically, such peptides have 23–37 residues and a net positive charge of +6 or more (see Table 1). In addition, many possess an amidated C terminus – a feature that further increases overall cationicity. SMAP-29, an α-helical cathelicidin-derived peptide of sheep, has unusually potent, broad-spectrum antimicrobial activity in vitro (Travis et al. 2000). Brogden and associates induced a *Mannheimia haemolytica* pneumonia in lambs and, 24 h later, administered 0.5 mg SMAP-29 directly to the affected part of the lung (Brogden et al. 2001; Kalfa et al. 2001). Twenty-four hours later, the experimental and control animals were euthanized and their lungs examined. The peptide-treated animals showed reduced inflammation and consolidation, and had lower numbers of bacteria in their bronchoalveolar lavage fluid.

Sites of cathelicidin synthesis and storage

The neutrophils of cattle store cathelicidin peptides in large cytoplasmic granules. The stored peptides remain inactive until their cathelin and antimicrobial domains

In the proline-rich peptide sequences, the proline residues are emboldened to accentuate their motifs. In the other peptide groupings, identical residues are emboldened, and similar residues are underlined. The asterisk (*) signifies carboxy-terminal amidation

are separated proteolytically by neutrophil elastase (Scocchi et al. 1992), which also activates cathelicidins in porcine neutrophils (Panyutich et al. 1997; Cole et al. 2001). In contrast, human PMNs activate their cathelicidin, hCAP-18, with another serine protease – protease 3 (Sorensen et al. 2001).

The cytoplasmic storage organelles of human and bovine PMNs differ in morphology and content. In human neutrophils, the primary ('azurophil') granules contain α defensins along with cathepsins, bactericidal/permeability-increasing protein (BPI), lysozyme, and several catalytically active neutral serine proteases (elastase, cathepsin G, and protease 3). The secondary ('specific') granules store hCAP-18, the cathelin-containing precursor of LL-37, along with lactoferrin, additional lysozyme, and B_{12}-binding protein. Bovine PMNs (and those of other ruminants) have an additional class of storage organelles called 'intermediate' granules. (Gennaro et al. 1983; Baggiolini et al. 1985). Intermediate granules serve as the main repositories for cathelicidins, are larger and more numerous than primary or secondary granules, and release their contents in response to phagocytosis or soluble stimuli (Gennaro et al. 1983; Baggiolini et al. 1985).

In an in vitro experimental system wherein hCAP-18 was misdirected into azurophil granules, it underwent premature proteolytic activation and released LL-37 (Bulow et al. 2002). Peptide purification and cloning have revealed at least seven different cathelin-associated antimicrobial peptides in bovine neutrophils: cyclic dodecapeptide, indolicidin, three α-helical peptides (BMAP-27, BMAP-28, and BMAP-37), and two proline-rich molecules (Bac5 and Bac7) (Scocchi et al. 1997). Similar studies in pigs have identified five protegrins, three proline-rich molecules (PR-39, prophenin-1, and prophenin-2), and three α-helical peptides (PMAP-23, PMAP-36, and PMAP-37) (Gennaro and Zanetti 2000; Zanetti et al. 2000).

CATHELICIDINS OF MICE AND MEN

In contrast to numerous cathelicidins in pigs, cattle, and ruminants, the human genome encodes only a single cathelicidin, hCAP-18, the antimicrobial domain of which is the 37-residue, α-helical peptide called LL-37. The gene is expressed constitutively in human neutrophils and the resulting propeptide is stored in its secondary (specific) granules. The murine homologue of hCAP-18 is CRAMP, an acronym for 'cathelin-related antimicrobial peptide (CRAMP)'. Adult mice express CRAMP transcripts in bone marrow, testis, spleen, and stomach. Their CRAMP gene maps to a region of mouse chromosome 9 that is syntenic to the loci of porcine and human cathelicidin genes. NMR spectroscopy of CRAMP in a membrane-mimetic solvent system revealed two amphipathic α helices (Leu4 to Lys10 and Gly16 to Leu33), connected by a flexible region between Gly11 and Gly16. Truncated CRAMP variants that contained its amphipathic carboxy-terminal region (Gly16 to Leu33) retained considerable antibiotic activity.

In human neutrophils, hCAP-18 and lactoferrin are about equally abundant on a molar basis (Sorensen et al. 1997). Other sites of hCAP-18 expression include epididymis, spermatids, various epithelial cells, and some lymphocytes. Expression of hCAP-18 in skin is inducible. The carboxy-terminal domain of murine CRAMP shows considerable homology to LL-37 but is somewhat shorter. Synthetic CRAMP inhibited the growth of a variety of bacterial strains (minimum inhibitory concentrations 0.5–8.0 μmol), and 1.0 μmol CRAMP permeabilized the inner membrane of *E. coli*. Knockout mice that do not express mCRAMP, the murine homolog of LL-37, show undue susceptibility to infection by group A streptococci (Nizet et al. 2001).

In addition to its antimicrobial properties, LL-37 binds bacterial LPS and can induce chemotaxis via the formyl peptide-like receptor-1 (De et al. 2000). A few mammalian α-helical cathelicidin peptides are shorter than LL-37 (e.g. porcine PMAP-23 and bovine BMAP-27), but most are about as long. Whereas the α-helical cathelicidin peptides of cattle and sheep have amidated carboxyl termini, those of rodents and primates do not. Although all the peptides shown in Table 1 are cationic, their net positive charges vary from +3 in porcine PMAP-37 to +14 in PMAP-36. Human LL-37 has 11 positively charged lysine and arginines, but its five negatively charged residues reduce its net charge to +6 and contribute to its poor activity against *Staphylococcus aureus* in media with normal or elevated concentrations of NaCl (Zhao et al. 2001a).

CATHELICIDIN GENES

Like other porcine and human cathelicidin genes (Agerberth et al. 1996; Gudmundsson et al. 1996), porcine protegrin and prophenin genes contain four exons and three introns (Zhao et al. 1995a, 1995b). Exon I encodes the signal sequence and the first 37 amino acid residues of the cathelin domain. Exons II and III code for 36 and 24 additional cathelin residues, respectively. Exon IV contains the final few cathelin residues followed by the protegrin sequence. This quadripartite gene structure suggests that expression of structurally diverse antimicrobial peptides on a common, cathelin-containing precursor occurred after mutational translocation of a suitable peptide domain into exon IV. Circumstantial evidence for such events is embedded in the sequences of the PR-39 and prophenin genes (Zhao et al. 1995a).

The upstream region of the PR-39 cathelicidin gene contains several potential recognition sites for NF-IL6 and acute phase response factor (APRF), as well as binding motifs for NF-κB, granulocyte–macrophage colony-stimulating factor (GM-CSF), and NF-1 – factors

that regulate gene responsiveness to cytokines and acute phase response factors. Site-directed mutagenesis studies also revealed a negative regulatory element in the 5′-flanking region of the PR-39 gene, suggesting a mechanism for its tissue-specific and age-dependent repression (Wu et al. 2000, 2002).

Bovine or porcine leukocytes each contain at least 10 different cathelicidins (Zanetti et al. 1995) whose structurally diverse C termini contain α-helical, β-sheet, proline-rich, tryptophan-rich, or other molecules (e.g. bactenecin dodecapeptide). In contrast to this polypharmacy, human and murine PMNs each contain a single cathelicidin: hCAP-18 in humans and CRAMP in mice. Neither human nor mice skin cells (keratinocytes) express hCAP-18 or CRAMP constitutively. However, production of both peptides is induced soon after injury (e.g. sterile incision) or infection. As it takes a few hours for epithelial cells to begin substantial cathelicidin production, the rapid infiltration of granulocytes affords protection in the interim (Hoffmann et al. 1996). LL-37 and HBD-2 are abundant in psoriatic skin, but their concentration in atopic skin lesions is considerably lower, perhaps contributing to diminished resistance to *S. aureus* infections in this setting (Ong et al. 2002).

The attributes of LL-37 and other cathelicidins may extend well beyond their core missions of exerting direct antimicrobial activity, and neutralizing the toxicity of LPS. Normal seminal plasma contains levels of hCAP-18 (40–140 μg/ml) that are 70-fold higher than those in blood plasma. Much of this hCAP-18 is on sperm cells, which carry about 6.6 million hCAP-18 molecules each (Andersson et al. 2002). Spermatozoa undoubtedly acquire their hCAP-18 coating in the epididymis, because high level hCAP-18 expression was noted in the body and tail of the epididymis (Malm et al. 2000). As the epididymis of humans (and mice) also expresses β-defensin genes, sperm may start their perilous journey equipped with something of a 'chemical condom' to dissuade any microbial hitchhikers from accompanying them on their journey (von Horsten et al. 2002; Yamaguchi et al. 2002). Alternately, the peptide could participate in later events directly associated with fertilization.

Studies by Oppenheim and associates have delineated a role of LL-37 and defensins as signals that link innate and adaptive immune responses. LL-37 acted via the Gi protein-coupled FPRL-1 (formyl peptide-like receptor-1) (Yang et al. 2001a, b) to induce a chemotactic response in human PMNs, monocytes and lymphocytes. The relatively high concentration of LL-37 needed to induce optimal chemotactic responses in peripheral blood monocytes was 10 μmol/l (about 50 μg/ml) which is likely to occur, if at all, only at sites of inflammation.

LL-37 was detected in freshly isolated lymphocytes and in supernatants of human T and natural killer (NK) cells grown with IL-2 for 5 days in vitro (Agerberth et al. 2000). Reverse transcription-polymerase chain reaction (RT-PCR) demonstrated LL-37 expression in B cells, γ, δ T cells, cloned NK cells, and monocytes, but not in αβ T-cell lines. Transcription and secretion of LL-37 by primary cultures of human lymphocytes responded to IL-6 and interferon-γ. Consequently, LL-37 (and defensins) may also contribute to the antibacterial activity of T cells and NK cells.

Some pathogenic bacteria may undermine host defense by inhibiting local production of antimicrobial peptides, including LL-37, e.g. early in human shigella infections expression of LL-37 and human β-defensin-1 was reduced or eliminated, with shigella plasmid DNA possibly being one of the mediators (Islam et al. 2001). If this were to promote bacterial adherence and invasion, it might enhance virulence.

CONCLUDING REMARKS

Interest in antimicrobial peptides has increased during the past decade, and they are now recognized as fundamental elements of the innate immune system. In addition to having direct effects on microbes, some of these peptides have prominent antiviral properties. In the case of α and θ defensins, our recent (and still largely unpublished) studies have found strong correlations between their antiviral activity and their ability to act as lectins that bind carbohydrate moieties present on viral glycoproteins and their cellular receptors. One wonders if the ability to recognize carbohydrates is also involved in their signaling and co-stimulatory properties. It seems likely that many surprises about the properties of these very old molecules will emerge during the decades to come.

Lipid mediators: leukotrienes, prostanoids and other lipids

CHARLES W. PARKER

Arachidonate metabolites 1
Other lipids with a known or possible signaling role 9
References 11

The lipid mediators are a complex group of biologically active metabolites with diverse effects on cellular metabolism, which particularly target the immune system, airways, and microvasculature. Most of them are produced from arachidonate in response to an immunological or nonimmunological stimulus. They tend to have a short half-life and to act in a paracrine or autocrine fashion. Arachidonate metabolites are typically present as mixtures in areas of immunological inflammation. They vary considerably in their cell(s) of origin, time of appearance, susceptibility to inhibition by pharmacological agents, potency, stability, and biological action, frequently exhibiting antagonistic effects (Parker 1984). None of them is stored in significant quantities and they are primarily products of activated rather than resting cells. They represent an important group of regulatory or modulatory agents whose actions in the control of cellular function are still being unraveled. Although this chapter emphasizes their role in immunological inflammation, gene disruption studies indicate that arachidonate metabolites have functions in virtually every organ, tissue, and cell (Funk 2001).

ARACHIDONATE METABOLITES

Major pathways of arachidonate metabolism

Arachidonate is a C_{20} fatty acid with double bonds at 5–6, 8–9, 11–12, and 14–15 positions (numbering from the carboxyl end). The multiplicity of double bonds helps explain its versatility as a biosynthetic precursor. As discussed below, the two major routes of arachidonate metabolism are the lipoxygenase and cyclooxygenase pathways. Lipoxygenases in mammalian cells act primarily at the 5–6, 12–13, or 15–16 double bonds of arachidonate (termed 5-, 12-, and 15-lipoxygenases, respectively). The five lipoxygenases produce the 5-hydroperoxide eicosatetraenoate (5-HPETE) that is metabolized to the slow-reacting substances (LTC_4, LTD_4, and LTE_4) and LTB_4 (collectively termed 'leukotrienes') (Figure 1). Cyclooxygenases oxidize and cyclize arachidonate, producing the endoperoxides PGG_2 and PGH_2 which are metabolized to the D, E, and F prostaglandins (PGD_2, PGE_2, and PGF_2), prostacyclin (PGI_2), and thromboxane A_2 (TxA_2) (Figure 2).
The term prostanoid is often used to describe the various cyclooxygenase products. As a result of the C_{20} fatty acid structure from which they are derived, the metabolites of arachidonate in the two pathways are collectively termed 'eicosanoids'.

Production of free arachidonate

Lipoxygenases and cyclooxygenases act largely or entirely on nonesterified arachidonate. As almost all of the arachidonate in cells is stored in ester linkage in phospholipids or triglycerides and much of the free arachidonate in the blood is bound to plasma proteins, esterified arachidonate must be released enzymatically at the time of cell activation. Recent evidence indicates

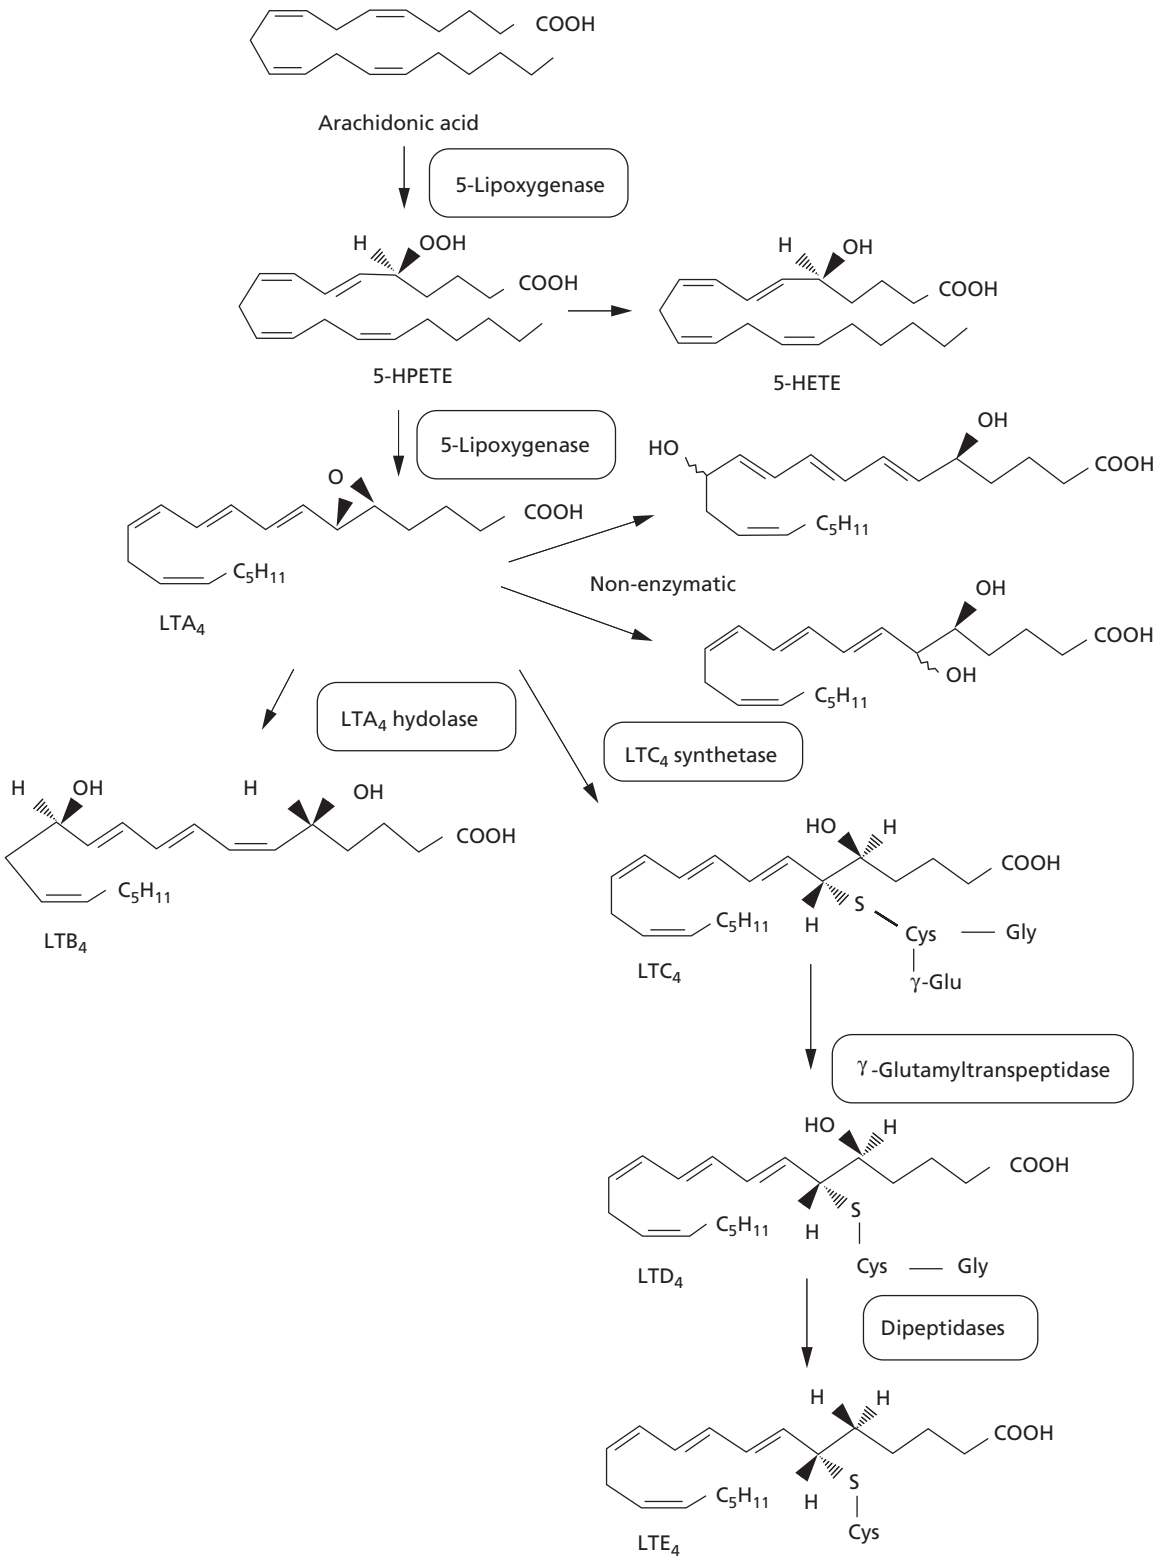

Figure 1 *Biosynthesis of leukotrienes. The enzymes involved are shown in boxes. HETE, hydroxyeicosatetraenoic acid; HPETE, hydroperoxide eicosatetraenoate; LT, leukotriene. (Redrawn from Figure 2, p. 5, of Nicosia et al. (2001) with the permission of the publisher Academic Press, Orlando, Florida.)*

that cytosolic phospholipase A_2 is an important enzyme in arachidonate release. Cells lacking this enzyme generally fail to produce eicosanoid metabolites (Funk 2001). Depending on the cell type, cell activation results in

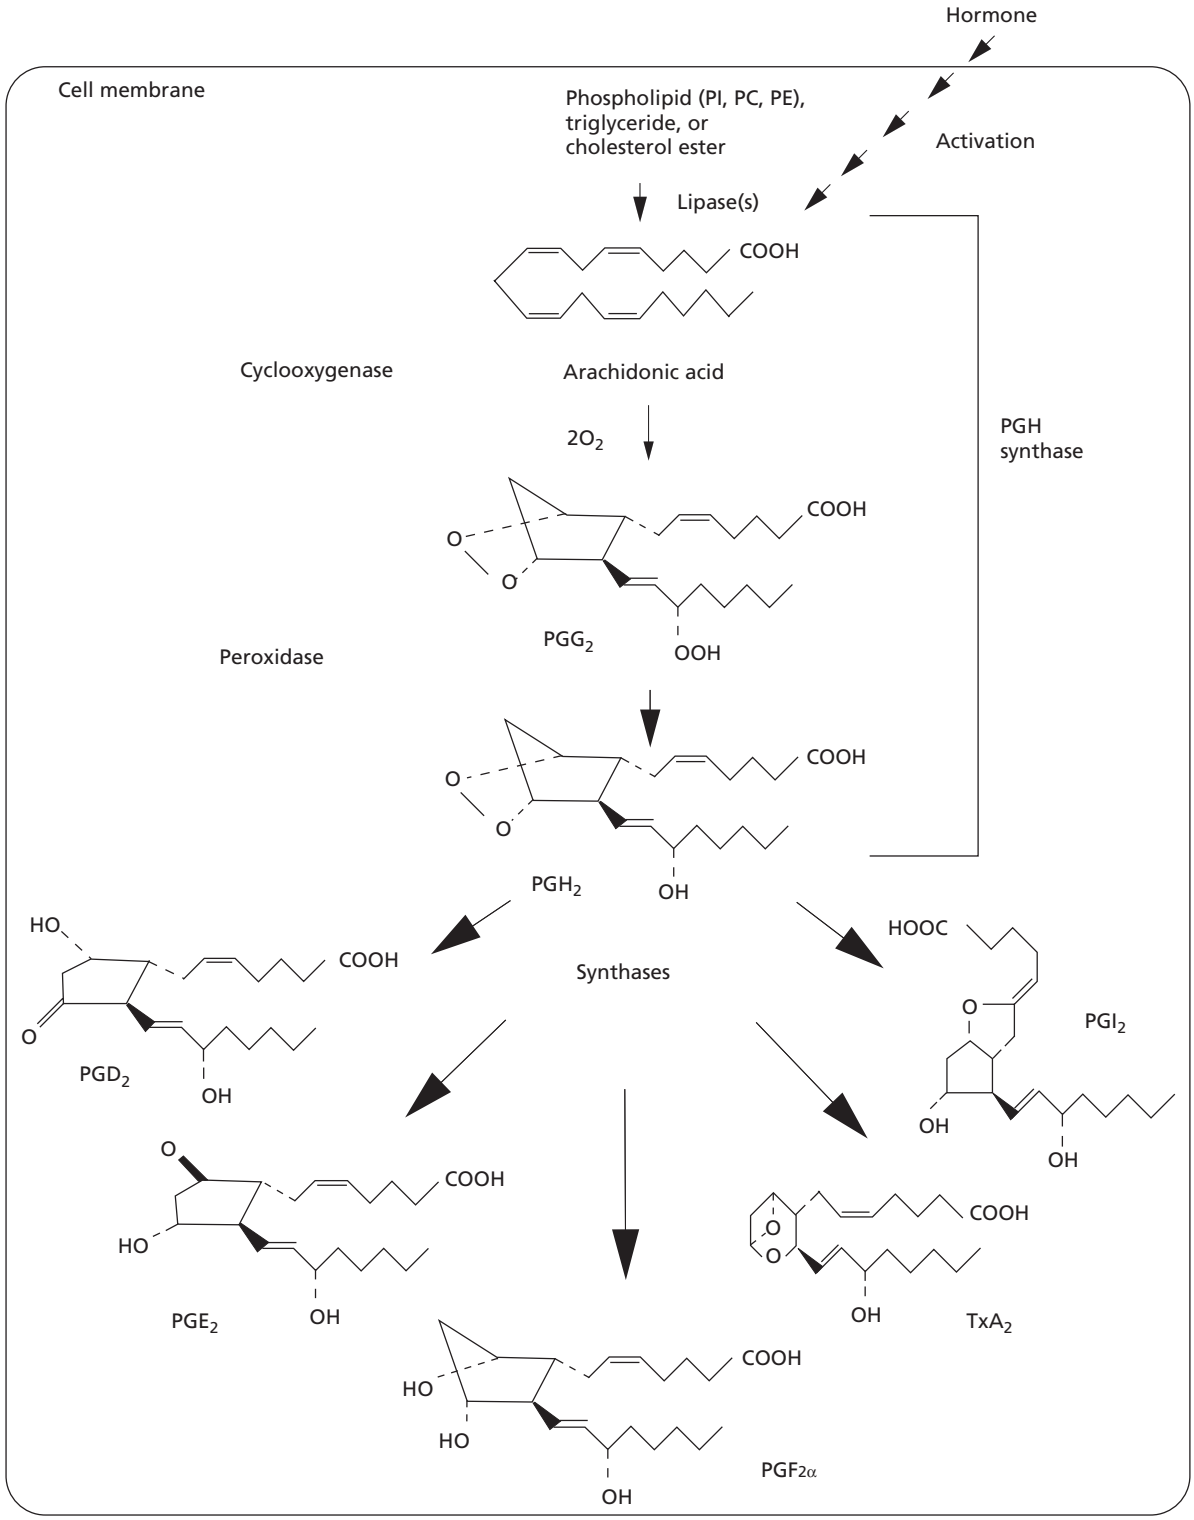

Figure 2 *Biosynthesis of prostanoids. The stimulus may be a hormone, antigen (antibody), or cytokine. Pg, prostaglandin; PGI , prostacyclin; TxA_2, thromboxane A_2. (Redrawn from Smith and Dewitt (1996), Figure 1, p. 168, with the permission of the publisher Academic Press, Orlando, Florida.)*

localization of this enzyme to the nuclear envelope, Golgi apparatus, or endoplasmic reticulum where it is thought to act locally to release arachidonate to nearby enzymes.

An important mechanism of glucocorticoid action is to inhibit phospholipase A_2 activity, decreasing the availability of free arachidonate, although eicosanoids vary

with respect to their susceptibility to steroid inhibition of their biosynthesis (Bisgaard 2000).

Lipoxygenases

Lipoxygenases add molecular oxygen to *cis*,*cis*-1,4-pentadiene moieties on long chain fatty acids, converting them to hydroperoxides and producing a rearrangement of the double bonds (Galliard 1975). Under special circumstances, fatty acid esters and alcohols are also substrates for these enzymes. The initial enzyme involved in leukotriene biosynthesis is a 5-lipoxygenase (Borgeat and Samuelsson 1979; Jakschik et al. 1977; Parker 1984; Samuelsson et al. 1987). This enzyme is primarily seen in mast cells, macrophages, eosinophils, and polymorphonuclear leukocytes, although basophils, endothelial cells, and epithelial cells also have activity (Parker 1987). It converts arachidonate sequentially to 5-HPETE and the 5,6-epoxide, LTA_4; LTA_4 is in turn converted enzymatically or nonenzymatically to LTC_4 (which has a glutathionyl side chain in thioether linkage at C_6), LTB_4 (a particular 5,12-diHETE diastereoisomer) or other diHETEs (see Figure 1). 5-HETE is also formed, probably primarily from 5-HPETE. The relative proportion of products depends on the cell type. Neutrophils contain leukotriene A_4 hydrolase which hydrolyzes LTA_4 to LTB_4, an important product in leukotriene function (Funk 2001). Mast cells contain LTC_4 synthase, which catalyzes the conjugation of LTA_4 to glutathione; neutrophils lack this enzyme and therefore produce little or no LTC_4.

The lipoxygenases that have been carefully studied all contain at least one atom of nonheme iron per enzyme molecule and this is also true of 5-lipoxygenases (Funk 2001). Lipoxygenases are subject to autocatalysis and autoinhibition, probably both caused by peroxides. Lipoxygenase product formation is rapid for the first 5–10 min after cell activation and then stops almost completely, even in the presence of excess exogenous arachidonate. In macrophages pretreated with lipopolysaccharide (LPS), 5-lipoxygenase activity can be downregulated for many hours apparently as a result of induction of nitric oxide synthesis (Coffey et al. 2000). The 5-lipoxygenases that have been characterized are calcium-dependent enzymes with a monomeric molecular weight of about 80 000 (Samuelsson et al. 1987). They have a segment in the N-terminal region capable of binding two calcium ions (Hammarberg et al. 2000). In nonactivated cells, most of the enzyme is in the cytosol in an inactive form, although depending on the cell some of it may be in the nucleoplasm. When the cell is activated and Ca^{2+} enters the cell, cytosolic 5-lipoxygenase presumably binds some of the Ca^{2+} and localizes in the perinuclear membrane where it associates with an activating protein (FLAP) and assumes full activity (Peters-Golden and Brock 2001).

Slow-reacting substances (leukotrienes C, D, and E)

Once LTC_4 is formed it is metabolized by peptidases to LTD_4 (cysteinyl-glycyl leukotriene) and LTE_4 (cysteinyl leukotriene). Collectively LTC_4, LTD_4, and LTE_4 constitute the activity originally described as slow-reacting substance (SRS). SRS was first described in 1938 as an activity obtained from guinea-pig lungs perfused with cobra venom enzymes which produced a characteristic, slowly evolving contraction of isolated guinea-pig ileal smooth muscle (Feldberg and Kellaway 1938). It was later shown to be present in sensitized guinea-pig lungs perfused by antigen. Working with a line of rat basophilic leukemia cells (RBL-1) that contain IgE receptors, our laboratory identified SRS as a mixture of arachidonate metabolites produced through the 5-lipoxygenase pathway (Jakschik et al. 1977; Parker 1982). We later showed that each of the SRS species had a sulfur-containing side chain and identified two of the three side chains as glutathione and cysteine (reviewed in Parker 1982). We also reported that the immunologically and nonimmunologically induced forms of SRS were identical in structure (Watanabe and Parker 1980). Samuelsson and his colleagues placed the sulfur at the 6 position and determined the location of the double bonds (Murphy et al. 1979). Orning et al. (1980) and Morris et al. (1980) definitively identified the cysteinyl-glycyl form of the molecule, for which we had earlier obtained suggestive evidence. Proof of structure and assignment of double bond configuration of LTC_4 were obtained independently by Hammarstrom et al. (1979) and Rokasch et al. (1980) by organic synthesis.

Once LTC_4 is formed, it is rapidly released into the cell medium, where it is normally metabolized to LTD_4 and eventually to LTE_4 by enzymes present in plasma, leukocytes themselves, and tissues (reviewed in Parker 1984). Release into the medium apparently involves the multidrug resistance transporter protein (Qian et al. 2001). The conversion to LTD_4 can involve conventional γ-glutamyl transferases, although recent evidence also implicates a distinct protease with a similar action (Drazen 2000). Once formed, LTD_4 is less rapidly converted to LTE_4 by various dipeptidases. These conversions are associated with substantial changes in biological activity. In chopped lung fragments or isolated leukocytes suspended in medium without serum or plasma proteins, the conversion to LTD_4 is ordinarily well under way within the first 3–5 min and, by 15 min, LTD_4 is the predominant SRS species that is present (Parker 1984). LTE_4 is generally not the most prominent SRS species until after 30 min. The sulfoleukotrienes can also undergo double bond isomerization or oxidation of the sulfur, leading to changes in biological activity; SRS metabolites and SRS itself (particularly LTE_4) are excreted to a significant extent in the urine

and bile in humans, and the levels of urinary LTE_4 correlate relatively well with disease activity in patients with asthma, especially if they are aspirin-sensitive (Bisgaard 2000; Nicosia et al. 2001).

The biological activity of SRS that has received most attention is its spasmogenic action on smooth muscle (reviewed in Parker 1983, 1984, 1987). Concentrations of LTD_4 as low as 0.1 pmol/ml produce readily detectable contractile responses on guinea-pig ileal and tracheal smooth muscle strips. On a molar basis, LTD_4 is about 60–100 times more active than histamine on the guinea-pig ileum. LTC_4 and LTE_4 are somewhat less active (by factors of 2 and 10, respectively, in the ileal system) but are still considerably more potent than histamine. In addition to its high potency, SRS produces an exceptionally sustained contractile response normally without tachyphylaxis, raising the possibility of a particularly prolonged action in vivo. Spasmogenic effects are produced on both the central and peripheral airways in humans and animals. LTC_4 and LTD_4 have been reported to constrict and dilate, respectively, cutaneous blood vessels, and decrease systemic blood pressure (Drazen et al. 1980). They also enhance cellular adherence, microvascular edema, mucus hypersecretion, and chemotaxis (especially of eosinophils) (James and Sampson 2001). The cysteinyl leukotrienes also promote granule enzyme release, although they are much less potent than LTB_4 in this regard (Goetzl 1980). Effects of leukotrienes (Öhd et al. 2000) and a 12-HPETE metabolite (Gu et al. 2001) on cell survival have also been described which is of interest with regard to the nuclear localization of active 5-lipoxygenase. The cysteinyl leukotrienes also exert a sustained effect on Purkinje nerve cell activity, which together with other evidence raises the possibility of important effects in the nervous system (Samuelsson et al. 1987).

Two types of receptors for cysteinyl leukotrienes have been identified and characterized: Cys LT1 and Cys LT2 (Drazen 2000; Maekawa et al. 2001). The Cys LT1 receptor is expressed in airway smooth muscle, macrophages, monocytes, eosinophils, and vascular endothelial cells. It has a higher affinity for LTD_4 than the other leukotrienes. The Cys LT2 receptor has an approximately equal affinity for LTD_4 and LTC_4. It is represented in peripheral blood leukocytes including eosinophils as well as in the lung, heart, adrenal medulla, and brain. Both types of receptors are members of the G-protein superfamily. The level of Cys LT1 receptor expression in human monocytes is upregulated by IL-4 and IL-13, suggesting a mechanism by which these cytokines might increase LTD_4 responsiveness and magnify the local response in IgE-mediated allergy (Thivierge et al. 2001).

There has been considerable activity in the pharmaceutical industry to develop drugs that prevent LTC_4 and LTD_4 formation or action. Both 5-lipoxygenase inhibitors and leukotriene LT1 receptor antagonists are now available for treatment of patients with respiratory allergy in Europe and the USA, and have been shown often to help relieve symptoms in chronic and acutely induced asthma (Nicosia et al. 2001). However, not all chronically asthmatic patients respond well and, as standard regimens not using these agents are often effective, more studies are needed for better definition of their precise role in treatment.

Dihydroxyeicosatetraenoic acids

LTB_4 is produced enzymatically from LTA_4 by a specific hydroxylating enzyme, although nonenzymatic hydrolysis may play a minor role (Samuelsson et al. 1987). When LTB_4 is purified from biological samples, several diastereoisomers of LTB_4 can be seen by high-pressure liquid chromatography or thin layer chromatography. These products appear to arise primarily by racemization of LTB_4 during purification. In general, the diastereoisomers are less active in biological systems than LTB_4 (Ford-Hutchinson et al. 1980).

As with cysteinyl leukotrienes, the major cell sources for LTB_4 in vitro are neutrophils, eosinophils, mast cells, monocytes, and basophils (Parker 1987; Nicosia et al. 2001), and the maximal response occurs within the first 5–10 min after cell activation. In neutrophils, much of the LTB_4 produced initially remains associated with the cells, but ultimately the bulk of the LTB_4 appears in the medium either as LTB_4 itself or as one of its metabolites (Stenson and Parker 1979). At 37°C human neutrophils rapidly metabolize LTB_4 to its 20-OH and 20-COOH derivatives, both of which are substantially less active in chemotaxis and granule enzyme release than LTB_4 itself.

LTB_4 stimulates chemokinesis in human neutrophils at concentrations of 1 nmol/ml or even lower (Ford-Hutchinson et al. 1980; Parker 1984), although substantially higher concentrations are required if plasma albumin, which binds LTB_4 is also present. The two major diastereoisomers of LTB_4 are considerably less active in this system. Although neutrophils are especially sensitive to LTB_4, cell movement is also stimulated in eosinophils, lymphocytes, and monocytes, indicating a general effect on leukocyte migration. LTB_4 also stimulates chemotaxis, although higher LTB_4 concentrations are needed (Goetzl 1980). At low nanomoles per milliliter concentrations LTB_4 also enhances lysosomal enzyme release from neutrophils, although as a rule this effect has required the concurrent presence of cytochalasins, casting some doubt on its physiological relevance. LTB_4 has little effect on vascular permeability but can enhance leukocyte adherence and emigration from the vasculature, resulting in part from upregulation of the expression of b_2-integrins (Wallace and Ma 2001).

Although early evidence indicated the presence of specific receptors for LTB_4 on human neutrophils (Kreisle and Parker 1983), it is only recently that the

genes involved have been identified. There is a high-affinity receptor termed BLT1 on leukocytes which acts though G-coupled proteins to stimulate chemokinesis, chemotaxis, and granule secretion (Serhan and Prescott 2000). Another LTB receptor, BLT2, has a considerably lower affinity for LTB_4 but is much more widely distributed. Evidence for the importance of LTB_4 and the BLT1 receptor in in vitro models of inflammation has been obtained in genetically manipulated mice that overexpress or fail to express this receptor (Serhan and Prescott 2000). One of the effects of overexpression of the BLT1 receptor was enhanced leukotriene biosynthesis, consistent with other evidence that LTB_4 is primarily a proinflammatory mediator. Specific antagonists for these receptors are under development.

Monohydroxyeicosatetraenoic acids

5-Hydroxyeicosatetraenoic acid (5-HETE) is quantitatively the major 5-lipoxygenase product obtained from leukocytes and mast cells (Parker 1984; Stenson and Parker 1979). It is formed from 5-HPETE and LTA_4 by spontaneous or enzymatic reduction. Peroxidases appear to be the primary enzymes involved in the enzymatic reduction. The mono-HETEs are less potent than SRS and LTB_4 in their known biological activities. Nevertheless, 5-HETE, 5-HPETE, and to a lesser extent the other mono-HETEs have significant chemokinetic and granule enzyme-releasing activities (Goetzl 1980; Stenson and Parker 1980). Although low micromolar concentrations are required to produce these effects, it is possible that the mono-HETEs are primarily active in the cells in which they originate. In neutrophils 5-HETE alone induces the release of specific granule enzymes. In mast cells and basophils, 5-HETE enhances antigen-induced histamine release but is not active by itself. Although the mechanism of 5-HETE action is not known, it and other monohydroxyl C_{20} acids have the very interesting property of being incorporated covalently into phospholipids and triglycerides (Stenson and Parker 1979). Even though the extent of this incorporation appears to be quite limited, localization of 5-HETE containing phospholipids in critical areas of lipid membranes could have important effects on local membrane fluidity and function (Parker 1984).

Other lipoxygenases and their products

The lipoxins are eicosanoids produced primarily in leukocytes by the combined or sequential action of 15- and 5-lipoxygenases (Samuelsson et al. 1987; Levy et al. 2001); 15-lipoxygenase activation is induced as a delayed response in leukocytes during inflammatory responses, caused at least in part by exposure to PGE_2 generated locally during cell activation (Levy et al. 2001). Once 15-HPETE has been produced, it is further metabolized to lipoxins, a group of 5,15-dihydroxy fatty acids with at least one additional hydroxyl group attached to the fatty acid chain; lipoxin formation sometimes involves collaboration between nearby leukocytes containing different lipoxygenases. Similar to PGE_2, lipoxins have both pro- and anti-inflammatory actions. Levy et al. (2001) have emphasized the anti-inflammatory effects of lipoxins proposing that they act primarily in the later stages of inflammation to reduce leukocytic infiltration and function. This may occur in part through an ability of lipoxins to stimulate phagocytosis of apoptotic leukocytes, removing them from the local environment.

Cyclooxygenases

In the cyclooxygenase pathway, oxygen is added enzymatically to arachidonate to form an unstable endoperoxide, PGG_2, with a cyclopentane ring derived from carbons 8–12 and a hydroperoxy group at the 15 position (Moncada et al. 1980; Calder 2001). The hydroperoxy group is then reduced by the same enzyme, producing PGH_2. Cyclooxygenase is frequently abbreviated as COX or PGHS for PGH synthetase. COX activity requires the presence of molecular oxygen and is promoted by a prosthetic heme group bound tightly to the enzyme (Smith and Dewitt 1996). Although COX exists in cells in a proactive state, there appears to be a requirement for at least some peroxide for enzyme activity. As the lipoxygenase system generates hydroperoxy fatty acids, which may in turn be reduced by glutathione peroxidase and other peroxidases, both of these enzymes may indirectly affect COX activity. There are two major classes of COX enzymes: COX-1 and COX-2; COX-1 is primarily a constitutive enzyme broadly represented in organs and tissues (Gianoukakis et al. 2001). It is responsible for basal prostaglandin (PG) synthesis. COX-2 is usually induced by synthesis from scratch of the COX-2 protein by hormones, growth factors, and cytokines. Induction occurs in immunocytes during immunological activation and is the major source of the increase in PGE_2 that accompanies immunological inflammation (Calder 2001). The COX-1 and COX-2 proteins are encoded by two very similar but distinct genes. The crystal structures of the two enzymes are almost identical but a critical amino acid difference leads to a larger substrate-binding pocket in COX-2 (Funk 2001). The two enzymes appear to be primarily localized in the endoplasmic reticulum and nuclear envelope, respectively (Smith and Dewitt 1996; Funk 2001), which may have important functional implications (see below).

PGG_2 and PGH_2 have half-lives in aqueous solution of about 5 min. Depending on the cell or tissue, PGH_2 may be converted to a PG, TxA_2, or PGI_2 and sometimes a mixture of two or more of these products is formed (Kleeberger and Freed 2000). PGG_2 can be

metabolized directly to PGD_2. Which of these products is made depends on the presence and level of activity of the appropriate enzyme systems (thromboxane synthetase, prostacyclin synthetase, 11-keto-isomerase, 9-keto-isomerase, and 9-keto-reductase) (reviewed in Parker 1984). In general, nonsteroidal anti-inflammatory agents such as aspirin and indometacin act primarily by blocking the COX, thereby reducing PGG_2 and PGH_2 formation. Therefore, they inhibit the synthesis of all of the eventual COX products. Nevertheless, the PG, TxA_2, and PGI_2 pathways are not necessarily inhibited equally. The degrees of inactivation depend in part on the relative K_ms of the individual enzymes involved in these subsequent metabolic conversions. Aspirin has a unique mechanism of action through acetylation of a critical serine residue on the enzyme. Most COX inhibitors act more or less equally on the COX-1 and COX-2 enzymes. Selective inhibitors of COX-2, rofecoxib (Vioxx) and celecoxib (Celebrex), are now in clinical use and still more selective inhibitors are under development (Funk 2001). The use of the selective COX-2 inhibitors reduces gastrointestinal side effects such as bleeding but the long-term advantages (and disadvantages) of such drugs are still not fully elucidated, particularly in individuals with other chronic diseases. None of the nonsteroidal anti-inflammatory agents can be regarded as completely specific for COX.

Prostaglandin metabolism and actions

The PGs are C_{20} fatty acids with a cyclopentane ring (see Figure 2). The E, F, and D PGs vary in the arrangement and type (hydroxy or keto and hydroxy) of substituents on the cyclopentane ring (Moncada et al. 1980). PG formation is associated with the loss of two double bonds, so prostaglandins derived from arachidonate have two remaining double bonds (e.g. PGE_2). PGH_2 is converted to PGD_2 and PGE_2 by a 11-keto-isomerase and 9-keto-isomerase, respectively. Both of these enzymes require glutathione. In addition to PGH_2, PGG_2 may be a substrate for 9-keto-isomerase. To a limited extent these conversions can be nonenzymatic because PGs can be formed by spontaneous breakdown of the endoperoxides. The existence of an isomerase for $PGF_{2\alpha}$ is doubtful. $PGF_{2\alpha}$ may be formed from PGE_2 by 9-keto-reductase or by direct reduction of PGH_2.

The PGs have long been known to affect blood vessel tone and promote smooth muscle contraction or relaxation, and they were originally postulated to be circulating hormones. However, it is now known that most of the PG in the circulation is rapidly metabolized, and it is generally agreed that PGs do not act as hormones affecting distant tissues (Moncada et al. 1980), except perhaps under exceptional circumstances. The major catabolic pathway for PG is by oxidation of the 15-OH group to the corresponding ketone by prostaglandin 15-OH-dehydrogenase (Kleeberger and Freed 2000). The 15-keto metabolite is then reduced to a 13,14-dihydro derivative. Subsequent metabolism is by β and terminal oxidation (Parker 1984). Enzymes that catalyze PG degradation are widely distributed in the body. One of the most active regions is the lung and, for example, more than 90 percent of infused PGE_2 is inactivated during a single passage through the lungs.

Leukocytes show marked differences in their abilities to produce PGs (Parker 1984; Kleeberger and Freed 2000; Funk 2001). Macrophages and monocytes make large amounts of PGE_2, substantial amounts of $PGF_{2\alpha}$, and very little or no PGD_2; neutrophils make moderate amounts of PGE_2 and little or no $PGF_{2\alpha}$ or PGD_2; mast cells make large amounts of PGD_2 and little or no $PGF_{2\alpha}$ or PGE_2. Resting lymphocytes or lymphocytic cell lines have been reported to make PGE_2 and less frequently to make $PGF_{2\alpha}$, but the amounts are quite small relative to monocytes and macrophages, and contamination of unstimulated lymphocyte preparations by monocytes may account for most or all of the PGs that are formed by these cells (Goldyne and Stobo 1979). However, when lymphocytes are stimulated by mitogens or appropriate cytokines, rapid induction of the COX-2 enzyme, with corresponding increases in PGE_2 production, may be seen, although the amounts of PGE_2 formed are not usually large. Originally TNF-α, IL-1, and IFN-γ were found to be stimulatory and IL-4, IL-10, and IL-13 inhibitory to enzyme induction (Berg et al. 2001). There is now evidence that IL-10 can be a potent inducer of COX-2 and PGE_2 production in LPS-stimulated mouse splenocytes. The induction is apparently produced indirectly through increases in cytokines that promote PGE_2 production. Surface stimuli including cytokines and antigens may also promote the production and release of PGs from monocytes and mast cells. As discussed below, the predominant effect of local increases in PGE_2 production may be to down-regulate ongoing immune responses.

One of the problems in interpretation of the data on PG formation has been the variation in results in different laboratories in the quantities or even the spectrum of arachidonate metabolites formed by a given cell type or mixture (Parker 1984). A study in human peripheral blood monocytes done many years ago (Bockman 1981) indicates that some of the discrepancies may involve differences in cellular sources and subsequent handling. The pattern of arachidonate metabolites formed by human peripheral blood monocytes cultured in vitro varied markedly with the duration of the culture following isolation of monocytes by cellular adherence. TxA_2 and PGEs were the major products on the first day of the culture. On the second day, PGEs were the major arachidonate metabolites and TxA_2 production was markedly diminished. Further changes in the spectrum of eicosanoids may be seen because monocytes continue to be maintained in tissue culture (Funk 2001).

Cellular differentiation, selective cell loss, restraints placed on the cells by the nutrient medium provided, and the accumulation of stimulatory and inhibitory cytokines may all affect arachidonate metabolite formation in this situation.

The biological effects of the PGs on immune function are quite diverse. PGE_2 is often the most active of the prostaglandins. In relatively high concentrations PGE_2 induces immature thymocytes and immature B lymphocytes to differentiate and acquire the functional, morphological, and immunological characteristics of mature lymphocytes (reviewed in Parker et al. 1974; Parker 1984), e.g. the addition of exogenous PGE_2 to thymocytes in vitro results in an increase in thymocyte cyclic adenosine monophosphate (cAMP) levels and thymocyte proliferation (Scheid et al. 1975). Other agents raising cAMP in these cells produce a similar response. PGE_2 affects erythropoiesis through direct effects on red cell precursors as well as by releasing erythropoietin from the kidney (Parker 1984). Some leukocyte precursors are not stimulated by PGE_2, e.g. macrophage colony formation is markedly inhibited. PGE_2 may also affect the differentiation of more mature cells, e.g. by the induction of collagenase secretion in apparently mature monocytes.

Once cells have matured, PGE_2 is primarily inhibitory exerting a variety of effects on leukocyte function, limiting inflammation (reviewed in Parker 1984; Calder 2001). PGE_2 has been reported to inhibit: (1) T- and B-cell proliferation; (2) leukocyte chemotaxis, chemokinesis, aggregation, spreading, phagocytosis, and oxidative metabolism; (3) cell-mediated cytotoxicity either by natural killer or cytotoxic T cells; (4) the release of inflammatory mediators from mast cells, basophils, eosinophils, and neutrophils; (5) production of cytokines, particularly IL-1, IL-2, IL-6, TNFα, and IFN-λ (Calder 2001) (although it has been suggested that PGs promote the T-helper (Th)2 cell pathway, in our laboratory PGE_2 and orally effective PGE_1 analogs are rapid and potent inhibitors of murine splenocyte IL-4 production, in vitro, apparently through a direct suppressive effect on IL-4 mRNA levels (Parker et al. 1995); and (6) inhibition of MHC antigen expression. Most of these effects are probably exerted directly on the responding cell preparations but indirect effects involving nearby cytokine producing cells undoubtedly also occur. While some of the inhibitory effects of PGE_2 require relatively high PGE_2 concentrations, others are produced at concentrations likely to be present at inflammatory sites in vivo. In a delicately regulated immune response, even relatively modest inhibitions may be significant, particularly if they are exerted selectively. In pharmacological concentrations in experimental animals, PGE and PGE analogs markedly suppress experimental inflammatory responses such as allograft rejection, immune complex glomerulonephritis, and the Arthus reaction (early work is reviewed in Stenson and Parker 1982). Orally effective PGE_1 analogs are being evaluated for their possible usefulness in a variety of therapeutic situations in humans.

Prostaglandins have proinflammatory as well as anti-inflammatory effects. Exogenously administered PGE_2 induces fever, erythema, increased vascular permeability, and vasodilatation (Moncada et al. 1980). PGE_2 is a very potent vasodilator. The dilatation is exerted throughout much of the microvascular bed. Although exogenously added PGs do not induce pain by themselves, they can markedly potentiate the pain and edema caused by bradykinin and histamine (Parker 1984). PGE_2 is found in increased quantities in inflammatory exudates at concentrations that can produce the classic signs of inflammation. Moreover, PGE_2 appears in experimentally induced inflammatory exudates over a time course consistent with its role as a mediator and PGE_2-binding proteins administered to arthritic joints have been shown to reduce local inflammation. A role for PGE_2 in arthritis seems particularly likely and this is supported by the widespread use of COX inhibitors in therapy in humans. PGs may also play a role in asthma and inflammatory bowel disease (Berg et al. 2001). $PGF_{2\alpha}$, 15-keto- $PGF_{2\alpha}$, and PGD_2 are potent constrictors of bronchial smooth muscle in humans and other animals (O'Byrne 1997). Subthreshold amounts of $PGF_{2\alpha}$ and PGD_2 increase overall airway reactivity. The bronchoconstriction involves both a direct effect on smooth muscle and an indirect effect through cholinergic pathways. PGE_2 and PGI_2 are bronchodilatory: PGE_2 may act in part by inhibiting the release of acetylcholine from airway cholinergic nerves.

By 2001 there were nine known PG receptor subtypes including four binding PGE_2 (EP_1–EP_4), two binding PGD_2 (DP_1 and DP_2), and one each binding $PGF_{2\alpha}$ (FP), PG_2 (IP), and TxA_2 (TP) (Funk 2001). All except DP_2 are members of the G-protein-coupled superfamily with seven transmembrane-spanning domains. Marked interspecies differences have been observed in the cellular distribution and function of some of these receptors (Kleeberger and Freed 2000). Most are located in the plasma membrane but several, including EP_1, are (or can be) in the nuclear envelope (Bhattacharya et al. 1998; Funk 2001). Selective effects involving individual PGE receptors have already been described, and it seems almost certain that the pattern will become more complex as studies continue. PGE_2 exerts most of its physiological effects through changes in intracellular cAMP. In many of the tissues or isolated cell systems in which it has been studied, PGE_2 stimulates adenylyl cyclase and increases intracellular cAMP concentrations. Many of its effects can be mimicked by cAMP agonists and analogs. However, effects through the EP_1 receptor apparently occur via increases in intracellular Ca^{2+} (Funk 2001) and stimulation through the EP_3 receptor is associated with decreases in cAMP. The F-type prostaglandins are generally less effective in raising cAMP

than the PGEs and, in a few tissues, stimulate increases in cGMP instead of cAMP; PGI_2, TxA_2, PGH_2, and fatty acid hydroperoxides may also affect cAMP or cGMP levels (Parker 1984).

Changes in the level of expression or location of the prostanoid receptors with time during an immune response in conjunction with evolving patterns of eicosanoid biosynthesis could importantly alter cellular responsiveness. Although PGs are normally thought of as having primarily a paracrine function, the evidence that the COX-2 enzyme is mainly localized in the perinuclear membrane where PG receptors may also be present is of interest for a possible additional autocrine action of PGs in the nucleus, perhaps affecting cellular replication or differentiation (Smith and Dewitt 1996). In this connection, cAMP localization has been demonstrated in the nucleus of human lymphocytes both in adenylyl cyclase studies of isolated nuclei and by cAMP immunofluorescence (Wedner and Parker 1977). Although nuclear cAMP accumulation was not stimulated by PG, only PGE_1 was studied and PG receptors might have been lost during the procedure used for the isolation of nuclei.

Thromboxanes

Thromboxane A_2 is a chemically labile C_{20} fatty acid with a six-membered oxygen-containing ring originally characterized structurally in platelet supernatants by Hamberg and Samuellsson (1974). It is produced from PGH_2 by the enzyme thromboxane synthetase. Thromboxane synthetase also catalyzes the conversion of PGH_2 to 12-hydroxy-5, 8, 10-heptadecatraenoic acid (HHT), a C_{17} hydroxy fatty acid formed by splitting off C9, C10, and C11 of the cyclopentane ring. The two products, TxA_2 and HHT, are formed in comparable amounts; HHT is unique in that it is the only simple hydroxylated eicosanoid that is not a lipoxygenase product. TxA_2 has a half-life in aqueous solution of about 30 s, spontaneously degrading to thromboxane B_2 (TxB_2) by the addition of water. As a result of this lability, it is almost always TxB_2 that is measured when thromboxane metabolism is studied.

Apart from platelets, macrophages and monocytes are the major known biosynthetic sources of TxA_2 (O'Byrne 1997). Mast cells and lymphocytes are poor sources of TxA_2, neutrophils make moderate amounts and platelets can account for about 95 percent of thromboxane detected in serum (Wallace and Ma 2001).

Stable endoperoxides mimicking TxA_2 action, inhibitors of TxA_2 synthetases, and TxA_2 receptor antagonists are now available and have helped to elucidate thromboxane's role (O'Byrne 1997). TxA_2 is a very potent vasoconstrictor, particularly in the rabbit aorta, but is also very effective in constricting tracheal and bronchial smooth muscle and has vasoconstrictor activity throughout the vascular system. Roles in asthma and in early and late bronchial responses to antigen have been suggested, but there appear to be major species differences and the effects of TxA_2 inhibitors in these situations have not been dramatic; TxA_2 has been implicated in late cutaneous responses to antigen in human skin. The best-defined functional action of TxA_2 on circulating cells is its ability to promote platelet aggregation (Hamberg and Samuellsson 1974). It may also have a role in neutrophil adherence. Inhibitors of thromboxane synthesis have been reported to reduce lectin-induced mitogenesis in human T cells in an apparent relationship with their potency as thromboxane inhibitors, raising the possibility that the thromboxanes play a positive role in mitogenesis (Parker 1984), but there has been little recent interest in this possibility. In contrast to PGI_2 and PGE_2, TxA_2 lowers intracellular cAMP concentrations, at least in platelets.

Prostacyclin

Prostacyclin synthetase catalyzes the conversion of PGH_2 to PGI_2, which in turn spontaneously degrades to 6-keto-$PGF_{1\alpha}$ by the addition of water (Moncada et al. 1980). Its half-life in aqueous solution at 37°C and neutral pH is several minutes or less. There is an interesting interaction between the lipoxygenase and cyclooxygenase pathways in that prostacyclin synthetase is inhibited by the hydroperoxy intermediates of the lipoxygenase pathway (Stenson and Parker 1982).

Prostacyclin is formed in vascular endothelium, macrophages, and mast cells (Humes et al. 1977; Kleeberger and Freed 2000). PGI_2 and TxA_2 frequently have adversarial roles and the relative amounts of these two agents may serve as a normal physiological control mechanism. PGI_2 is a potent vasodilator and inhibitor of platelet aggregation and, given intravenously in small quantities, produces systemic hypotension. Levels of the prostacyclin metabolite, 6-keto- $PGF_{1\alpha}$, are elevated in the inflammatory exudates of chronic granulomas (Parker 1984). In addition to its potency as a vasodilator, PGI_2 increases vascular permeability directly and potentiates the increased vascular permeability induced by other inflammatory mediators. PGI_2 is also a potent inducer of pain. Most or all of PGI_2's effects on tissue and cells appear to be mediated through increases in cAMP.

OTHER LIPIDS WITH A KNOWN OR POSSIBLE SIGNALING ROLE

Isoprostanes

Isoprostanes are isomers of conventionally derived PGs, which are produced primarily by a free radical attack on esterified polysaturated fatty acids in cell membranes,

especially arachidonate (Pratico et al. 2001). They are generated in situ under conditions of oxidant stress and then released, presumably by phospholipase. The F_2 isoprostanes (isomers of $PGF_{2\alpha}$, designated as F_2-iPs) have been the most frequently studied, but analogous isomers exist for other PGs and LTs. In addition to being markers for lipid peroxidation a number of the isoprostanes have reasonably potent biological activities, e.g. $iPF_{2\alpha}$ III produces bronchoconstriction, vasoconstriction, and platelet aggregation, apparently by stimulation of the TxA_2 receptor, at relatively low concentrations. The role of isoprostanes in inflammatory processes in vivo is still uncertain.

Lipid metabolites resembling eicosanoids

In general, LTs and PGs are produced predominantly from arachidonate. However, long-chain polyunsaturated fatty acids other than arachidonate also have to be considered as sources of biologically active lipids. They are present in cell membranes and may be substrates for enzymes in the various lipoxygenase and COX pathways, depending on their availability for rapid release as free fatty acids, structure (location of the double bonds, number of carbon atoms), and the capabilities of the individual enzymes. The resulting products are as a rule formed in relatively limited quantities. Moreover, they are altered in their double bond structure or number of carbons and tend to be less potent biologically than the usual LTs and PGs (Calder 2001). They may assume increased importance when the fatty acid content of cells has been manipulated in vivo by diet. Animals on diets rich in eicosapentaenoic, docosahexaenoic, oleic, or linoleic acids in general show less active responses in experimental models of inflammation than animals on the usual laboratory diets. Known or suspected mechanisms include decreases in the arachidonate content of cells that reduce its availability as a substrate, competitive inhibition of arachidonate-metabolizing enzymes by nonarachidonate fatty acids and their metabolites, and possible effects through alterations in cellular function, which may include changes in enzyme or receptor expression directly affecting eicosanoid metabolism or action. A considerable literature already exists on the possible usefulness of such diets in treating immunological diseases in humans.

Platelet-activating factor

Platelet-activating factor (PAF) is a family of structurally closely related, chemically stable neutral lipids containing a glyceryl core, a phosphorylcholine head group at the 3 position, one of several long-chain alkyl ethers (especially hexadecyl or octadecyl) at the 1 position, and an esterified acetyl group at the 2 position (Pinckard et al. 1982). 1-Alkyl,2-acyl-phosphatidylcholines, in which the acyl group is oxidatively fragmented, may also have PAF-like activity (Prescott et al. 2000). Studies of the aggregation response of rabbit platelets with analogs of PAF indicate that all three of the groups attached to the glyceryl backbone are important for its aggregating activity (Demopoulos et al. 1979). Replacement of the alkyl group at the 1 position by a carboxylic acid ester of the same chain length results in a 250-fold decrease in activity. The naturally occurring analog of PAF with a 16:0 alkyl group has about five times the activity of 18:0 alkyl-PAF. Replacement of the 2-acetyl group with butyryl reduces activity about 10-fold, whereas lyso-PAF has no activity even at very high concentrations. Removal of the choline or phosphorylcholine group results in a decrease in activity of more than 1000-fold.

Platelet-activating factor is not prestored. There are two known pathways of PAF biosynthesis. One is a pathway from scratch in which the final step is the addition phosphorylcholine to 1-alkyl,2-acetyl-glycerol (Watson and Snapper 1997). Such synthesis can account for most of the low-grade constitutive synthesis of PAF that is seen in some tissues. In the second, generally more important remodeling pathway, preexisting 1-alkyl,2-acyl-phosphatidylcholine is deacylated at the 2 position to form the corresponding lysophosphatidylcholine (or lyso-PAF) which in turn is acetylated by an acetyl-CoA-lyso-PAF-acetyl transferase to form PAF. The remodeling pathway predominates when PAF is generated in response to an acute or chronic cellular stimulus. As with the eicosanoids, cytosolic phospholipase A_2, which preferably acts on *sn*-2-arachidonyl residues in phospholipids, plays a key role (Prescott et al. 2000). Thus eicosanoid and PAF biosynthesis tend to occur together.

Production of PAF in response to cellular stimuli occurs rapidly, with significant activity usually being generated in less than a minute. Originally PAF action was thought to require its release from cells. Although activity does appear in the medium of cells stimulated in vitro and the free PAF is active, the extent of this release varies with the cell type. Vascular endothelial cells retain most of their PAF activity on their surfaces (Prescott et al. 2000). In this position the PAF interacts with PAF receptors on nearby intraluminal leukocytes, resulting in their immobilization and metabolic activation. P-selectin participates importantly in the immobilization process. PAF production tends to fall off rapidly, probably resulting in part from limitations in alkylphospholipid precursor availability, which varies considerably in different tissues. Once formed the PAF is rapidly degraded, much of it within a few minutes. The major mechanism for inactivation both inside and outside the cell is enzymatic deacetylation. Extracellular PAF acetyl hydrolases are present primarily in the lipoprotein fractions of human and animal plasma (Pinckard et al.

1982). At least three isoforms of the enzyme exist intracellularly (Prescott et al. 2000) and all forms of the enzyme are serine proteases inactivated by diisopropylfluorophosphate. As PAF production falls off rapidly with time, PAF is quickly degraded and receptor desensitization tends to occur rapidly, PAF actions typically are brief. However, in ongoing inflammatory responses in vivo newly arrived cells may help continue the response.

Platelet-activating factor is produced in many different cell types and tissues, usually in response to an immunological or nonimmunological stimulus. Immunological stimuli producing PAF include antigen and antibody, cytokines, and other mediators. Immunocytes including monocytes, macrophages, neutrophils, basophils, and eosinophils (Watson and Snapper 1997) are significant sources with small amounts being made by lymphocytes, mast cells, and platelets. Vascular endothelial cells are an important site of PAF production. The best-characterized effects of PAF (and stable PAF-like agonists) are on vascular reactivity and inflammation (Watson and Snapper 1997; Prescott et al. 2000; Wallace and Ma 2001). PAF stimulates: (1) platelet aggregation; (2) leukocyte aggregation, chemotaxis, and secretion; (3) airway and intestinal smooth muscle contraction; and (4) microvascular leakage and spasm. PAF may also induce the production of more effective action by other mediators and cytokines. There is substantial species variation in PAF actions. Aggregation responses of rabbit platelets and neutrophils occur at subnanomolar concentrations of PAF but human platelets are considerably less susceptible. The rapid intravenous infusion of as little as 2.5 μg of PAF in adult rabbits results in the almost immediate induction of marked neutropenia, thrombocytopenia, hypotension, and respiratory obstruction, culminating in respiratory arrest and death within minutes (McManus et al. 1980). At lower, nonfatal doses of PAF, the decreases in circulating platelets and neutrophils are reversible but animals show aggregates of platelets and neutrophils in pulmonary vessels and pulmonary arterial hypertension. Similar changes occur in sensitized rabbits undergoing fatal or nonfatal systemic anaphylaxis. Most of the effects of systemically injected PAF in experimental animals probably do not involve mechanical obstruction as such. In addition to direct effects on vessel walls by PAF, PAF may in part act by stimulating the secretion of TxA_2 and LTs (Pinckard et al. 1982) by platelets and leukocytes. The bronchoconstrictor effects of aerosolized PAF also appear to have complex mechanisms. PAF may have physiologically significant actions on cutaneous vascular reactivity. On a molar basis PAF is 10–1000 times more potent than histamine in producing acute weal-and-flare reactions in human and animal skin. Important actions outside the immune system in the brain and elsewhere are also suspected (Prescott et al. 2000).

The PAF receptor is a G-linked protein that is expressed on the surfaces on a variety of cell types (Prescott et al. 2000) and the receptor has a number of conformational states with various affinities. Most of the available PAF antagonists act by reversibly competing with PAF for the receptor. They include products present in Chinese herbal medicines that have long been used in the treatment of asthma (Watson and Snapper 1997). Despite evidence that PAF may participate in the pathogenesis of asthma, used by themselves, PAF antagonists have not been shown to be consistently helpful in the treatment of asthma.

Despite its potency and diverse actions PAF is produced in association with other mediators and is rapidly metabolized, complicating studies of its role in vivo; however, studies on genetically manipulated animals with increased or absent PAF receptor expression, or impaired PAF degradation, are now available (Prescott et al. 2000). Taken together with pharmacological studies with PAF receptor antagonists and inhibitors of PAF synthesis, they indicate that the PAF system is probably not normally essential for physiological well-being. However, PAF clearly can have substantial modulating roles affecting airway reactivity, anaphylaxis, endotoxemia, and local inflammation. Not enough is known about the role of PAF in local resistance to serious acute and chronic infections. Excess PAF activity is a potential problem and humans with defective PAF catabolism appear to be at increased risk for severe asthma and neonatal necrotizing enterocolitis.

INTRODUCTION

In this chapter the aim is to explain the changes that occur as a local inflammatory response becomes sufficiently strong to start causing systemic changes. The term 'acute phase response' is frequently used to encompass all the changes that occur in different organs when inflammation becomes systemic, indeed some of the most common manifestations of severe illness are components of the acute phase response. Fever, somnolence, and confusion represent some of the behavioral or physiological changes that are easily observed, whereas analysis of the biochemical, immunological, or metabolic alterations has demonstrated an array of changes that take place.

The acute phase response (APR) is a conserved response and it is rare to find individual patients who have an inability to mount components of the response. This is not surprising as the response is vital for homeostatic effects and protection against infection. There is an argument that one of the most powerful selective pressures evolutionarily is infection so that, whether or not the acute phase function response was directly protective or homeostatic, most of the responses seen are likely to counter infection. Over the last few years, the amount of investigation into the APR has been dwarfed by the efforts afforded to the cytokine initiators of the APR. These are the proinflammatory cytokines that generate the APR. These cytokines and other inflammatory mediators, which act at a local level, are also responsible for effects at the systemic level. In this chapter the role of these inducers is reviewed, concentrating on systemic responses rather than purely localized responses. The APR could be considered to include circulating cytokine responses to inflammation because they are also part of the overall systemic inflammatory response. One further aspect of the acute phase response is that many of the changes that occur and are present in an acute episode of inflammation will also be present in a chronic inflammatory disease. Thus, the name acute phase response is not really ideal because it is also a phenomenon of chronic inflammation, and an alternative term is the 'systemic inflammatory response syndrome (SIRS)'. This term is often used to describe severe clinical situations, however, and sepsis is used if the cause is infectious.

One of the most interesting aspects of the APR is the increase in acute phase proteins (APP) synthesized mainly in hepatocytes (Kushner 1982). Although normally considered to be a function of the liver, the definition of APP is not entirely limited to hepatic synthesis, because many APPs are synthesized outside the hepatocyte. Aspects of the APR are found in many different cells and sites in the body.

In this review, the APR to inflammation of any cause is considered although the concentration is on infectious examples where appropriate. It has to be remembered, however, that some of these proteins described are likely to contribute to homeostasis in many noninfectious situations and many may have more than one function. The aim is to cover mechanisms by which responses are stimulated, what is known about the func-

Table 1 *Major aspects of the acute phase response*

Metabolic aspects
Loss of muscle and negative nitrogen balance (protein catabolism)
Decreased gluconeogenesis (lactate, etc. no longer converted to glucose)
Osteoporosis (in chronic inflammation)
Increased hepatic lipogenesis
Increased lipolysis in adipose tissue
Increased triglycerides in serum and decreased high-density lipoprotein
Cachexia
Increased requirement for glutamine in fast-dividing immune cells, possibly leading to deficiency of glutamine
Micronutrient changes
Reduced serum zinc, iron, and copper
Reduced plasma retinol
Increased glutathione concentrations
Hemopoietic changes
Reduced red blood cell numbers
Increased neutrophils
Increased platelets
Neuroendocrine changes
Fever
Somnolence
Increased corticotropin-releasing hormone, corticotropin, and cortisol
Increased secretion of arginine vasopressin
Decreased insulin-like growth factor 1
Increased secretion of catecholamines
Hepatic changes
Positive and negative acute phase proteins
Increased metallothionein, heme oxygenase, etc.

tion of these responses, and where responses may malfunction. The major aspects are summarized in Table 1.

INDUCTION OF THE ACUTE PHASE RESPONSE

Induction of systemic inflammation

The APR is a nonspecific response in that it can be initiated by many different stimuli although, regardless of stimulus, the magnitude of the response is dependent on the extent of injury. Such injury may be caused by burns, irradiation, surgical or physical trauma of tissue injury or infection. Infection is often a strong inducer of the response, and particularly bacterial infection, because of the range of powerful immune stimulators that bacteria possess. More recently, when more sensitive assays were used to measure markers of inflammation such as C-reactive protein (CRP), associations were observed in a number of diseases that were previously not thought of as inflammatory in nature, such as atherosclerosis (Haverkate et al. 1997; Libby et al. 2002). This may be extended to other diseases in time. At the lower end of the spectrum of stimulus, strenuous exercise such as marathon running (Vider et al. 2001) or some psychiatric illnesses or stress (Maes et al. 1997) may cause a mild APR, at least detectable through the more sensitive indicators of the acute phase.

The initial stimulus for the APR may be physical trauma, through other means of tissue damage, or through adaptive immunological mechanisms including allergen and IgE-mediated mechanisms, immune complex activation of phagocytic cells, or T-cell-mediated recognition. Alternately, infection can be recognized by an increasing range of innate mechanisms such as endotoxin or peptidoglycan activation through Toll-like receptors (TLR) or other pattern recognition molecules. It is now known that such pattern recognition molecules can recognize many different foreign structures including nucleotide, protein, carbohydrate, and lipid structures. Following such stimuli, tissue injury may at first cause changes in vascular permeability through short-lived lipid mediators such as prostaglandins and leukotrienes, which allow fluid to leak from the post-capillary venules into the tissues. This is accompanied by a chemotactic stimulus from a variety of factors that bring inflammatory cells such as neutrophils, and subsequently macrophages, into the inflammatory site. The chemotactic stimulus works in conjunction with expression of adhesion molecules on the endothelium and leukocyte to control this cellular influx. These include the chemokines such as interleukin-8 (IL-8) which attracts neutrophils. The inflammatory cells themselves contain or synthesize a number of proinflammatory activators, many small and short-lived, but in addition some proinflammatory cytokines are generated that have the ability to transmit the inflammatory signal over much larger distances.

Different aspects of the APR take a different length of time to be observed following a defined stimulus. The induction of some of the APPs, for instance, may take between 24 and 72 hours to reach their peak (Figure 1b) whereas effects such as fever and malaise may be more rapidly observed. The main reason for such delays is that several rounds of inducible protein synthesis may be required. The proinflammatory cytokines such as tumor necrosis factor-α (TNFα) and interleukin-1 (IL-1α or IL-1β) can be generated within an hour or two of the start of the stimulus. TNFα is usually induced (largely through post-transcriptional regulation) earlier than IL-1β but both then induce a number of other cytokines (Figure 1a). If the stimulus for inflammation continues to be present at a sufficient level then the proinflammatory cytokines TNFα and IL-1β (more than IL-1α) are released into the circulation and induce responses at distant sites. In addition to release of such cytokines, early responses involve the release of a range

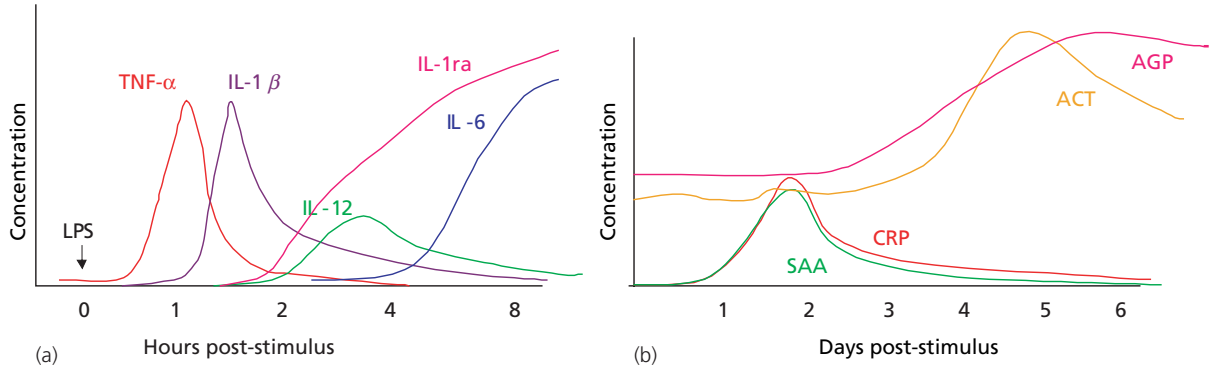

Figure 1 *Time course of induction of* **(a)** *cytokines and* **(b)** *acute phase proteins after an acute inflammatory stimulus such as lipopolysaccharide (LPS). ACT, antichymotrypsin; AGP, acid glycoprotein; CRP, C-reactive protein; IL, interleukin; SAA, serum amyloid A; TNF, tumor necrosis factor.*

of different chemokines, each with their own spectrum of cell attraction properties. These chemokines influence the range of cells entering the site of inflammation and thus the course of the inflammatory response. These early cytokines will in turn give rise to other cytokines that they induce at local and distal sites, such as IL-6 which frequently mediate cellular responses (Figure 1a). Other cytokines take rather longer to be synthesized and in some cases are no longer proinflammatory and some, such as IL-10 and IL-1 receptor antagonist (IL-1ra), are definitely anti-inflammatory. The overall effect is sometimes referred to as a cytokine 'storm' – a useful phrase because it reflects the battery of new stimuli to which cells are subjected.

Proinflammatory cytokines and the acute phase proteins

As an example of how the APR is generated hepatocyte production of APPs is the main focus because this is comparatively well known. Other aspects are considered later. The induction of the APR in the liver was studied extensively as a model of gene expression. The major cytokine involved in induction of the APR is IL-6. IL-6 was originally also called hepatocyte-stimulating factor (among other names), based on its inducing properties (Gauldie et al. 1987). This cytokine is the most prominent member of a family of cytokines (oncostatin M, leukemia inhibitory factor, ciliary neutrotrophic factor, IL-11, and cardiotropin 1) that can all induce the APR. This family of cytokines binds a family of receptor complexes containing a cytokine-specific receptor component chain, as well as a common component chain called gp130. It is the gp130 that has the major signaling role in the complex, which responds by transmitting a signal when homodimerized (Paonessa et al. 1995). Interestingly, the soluble IL-6R (sIL-6R) acts as an agonist and continues to help induce responses to IL-6 if gp130 is expressed on the cell surface (Mackiewicz et al. 1992). In addition, the sIL-6R–IL-6 complex has a longer half-life, thus stabilizing the activity of IL-6 (Peters et al. 1996). The soluble gp130, on the other hand, inhibits the response (Jostock et al. 2001). The other major inducer of the APR is IL-1. This cytokine family has many members but three are relevant to the induction of APPs. IL-1β is probably the most important inducing form because it is the major serum form of active IL-1. IL-1α is thought to be more important at a local level and the other form of IL-1 is an antagonist form called interleukin-1 receptor antagonist (IL-1ra) which can bind to receptor but does not activate or recruit the accessory chain (Hannum et al. 1990; Greenfeder et al. 1995). IL-1β binds to two receptors: IL-1R1, which is capable of inducing response, and IL-1RII, which is a decoy receptor with no ability to signal (Colotta et al. 1993). Very few receptors need be occupied for a cell to respond to this cytokine but receptor numbers are regulated during the APR. Responses to IL-1 are thus kept under control by a number of systems (Mantovani et al. 2001).

The APPs have been classified as class I or class II based on the cytokines to which they respond (Figure 2). The class I APPs are induced by IL-1-type cytokines such as IL-1β or IL-1α (as well as TNFα and TNFβ) and IL-6. The TNF cytokines are included in this definition because they induce some of the same signaling and transcription factors as IL-1. The class II APPs, on the other hand, are induced almost exclusively by IL-6 and other members of that family of cytokines (mainly through IL-6RE which bind the STAT transcription factors). In some cases IL-1 may even reduce responses, for instance although IL-6 induces fibrinogen this is inhibited by IL-1β or TNFα (Rokita et al. 1994). The use of mouse IL-6 knock-out animals has confirmed the important role of IL-6 but this revealed another feature of the APR. Although turpentine-induced inflammation could not induce an APR in these animals, induction with lipopolysaccharide (LPS) led to an almost normal APR. This may be caused by induction of a different range of cytokines that can make up for the lack of IL-6 (Fattori

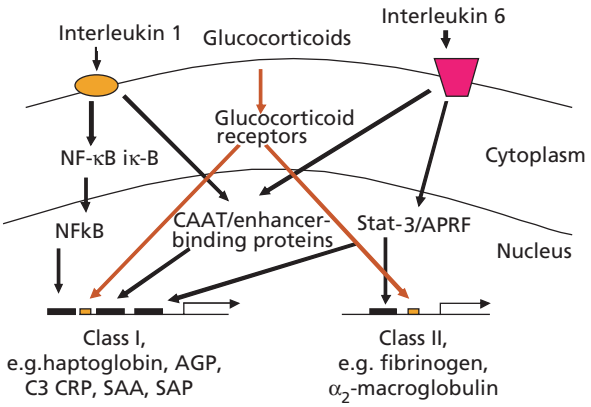

Figure 2 *Simplified pathways of induction of acute phase protein genes. AGP, acid glycoprotein; CRP, C-reactive protein; SAA, serum amyloid A; SAP, serum amyloid P.*

et al. 1994; Kopf et al. 1994). The likely candidates are other members of the IL-6 family of cytokines but leukemia inhibitory factor (LIF) and IL-11 are not likely to be involved (Gabay et al. 1996). Interestingly, the same sort of pattern is seen in IL-1β knock-out mice with responses to turpentine being lost but LPS maintained (Zheng et al. 1995). IL-6 production in response to IL-1 is diminished after turpentine injection. Other knock-out mice lacking IL-1-converting enzyme (caspase-1) show no reduction in responses to LPS or local turpentine (Fantuzzi et al. 1997). The loss of the signaling molecule gp130 in mice leads to severe abnormalities in development and immune cells making interpretation difficult. It has been seen, however, that loss of the signaling component STAT3 (downstream of gp130 signaling) leads to complete loss of induction of some class I acute phase genes which have regulatory elements for C/EBP transcription factors. Type II APPs were reduced at 24 hours but earlier responses are maintained (Alonzi et al. 2001). Some APPs (complement C3 and SAA3) have no STAT3 regulatory regions and are not affected by its loss. Adaptor proteins that bind STAT3 such as STAP-2 (BKS) also have significant roles in regulating signaling for APP synthesis (Minoguchi et al. 2003). Synthesis of each APP gene is regulated both transcriptionally and post-transcriptionally. The transcriptional regulation is controlled by the range of nuclear factors that bind to the promoter regions of the protein gene. Some of these are induced by IL-6 such as NF–IL–6 and others such as NF-κB are induced by TNFα or IL-1β (Edbrooke et al. 1989; Akira et al. 1990). Often such factors may act synergistically, e.g. the combinations of IL-6 and IL-1 for synthesis of serum amyloid A (SAA). In addition, some proteins are also strongly regulated post-transcriptionally by stabilization of the mRNA and this occurs for instance for α acid glycoprotein (AGP) (Shiels et al. 1987). The regulation of each protein is, however, complex and unique, e.g. a range of transcription factors has been identified in the induction of SAA genes including NF-κB, C/EBP, AP-2, Sp1 and YY1, and SAF (Uhlar and Whitehead 1999).

Lipopolysaccharide has been reported to activate hepatocytes directly, although it is hard to rule out the possibility that this is an indirect effect through LPS-induced cytokines. Thus, some questions remain that are unresolved with regard to induction of the hepatic response. Can the hepatocyte, if it expresses Toll-like receptor 4 (TLR4), respond to LPS directly? And if not, what role do the nonparenchymal cells of the liver have in directing the hepatocyte response? In particular, what contribution to the IL-6 stimulus to the hepatocyte comes from the Kupffer cell or possibly even the endothelial cell or fibroblast, and what contribution comes from circulating cytokine? Histological studies of mRNA or protein synthesis in liver sections has revealed a pattern of synthesis that involves initial synthesis in periportal regions followed by spread to perilobular, midlobular, and centriolobular regions until, at peak serum CRP, almost all hepatocytes are synthesizing CRP (Kushner and Feldmann 1978) (Figure 3). It should also be remembered that control can be exerted at the secretion stage as, for instance, for CRP (Yue et al. 1996). As referred to later, under Protein metabolism, the hepatocyte requires an increased supply of

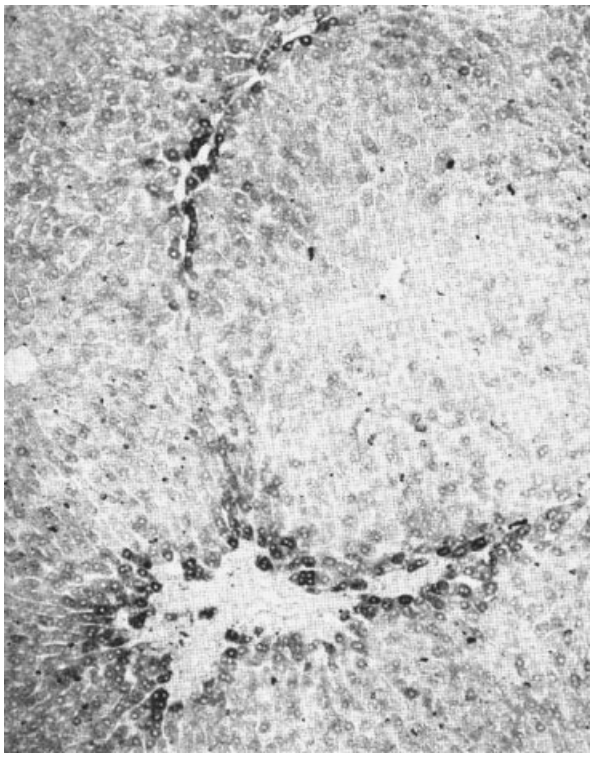

Figure 3 *Immunoenzymatic identification of hepatocytes producing C-reactive protein (CRP) 8 h after an inflammatory stimulus. Perilobular and periportal areas show intense cytoplasmic staining. (Reproduced from Kushner and Feldmann 1978, with permission.)*

amino acids for this increased burden of protein synthesis, and thus amino acid uptake by hepatocytes is increased.

Influence of inhibitory or modulating factors on APPs

Although glucocorticoids are generally an anti-inflammatory influence, it is also clear that they enhance synthesis of many APP genes (Baumann et al. 1989). The presence or absence of glucocorticoid response elements controls the extent of response to glucocorticoids which varies between proteins with, for instance, AGP being very strongly dependent on these hormones.

As IL-1 is a major inducing factor, it is not surprising that IL-1Ra would have an inhibitory action because it increases at a later time point in the APR subsequent to IL-1β. IL-1ra can reduce synthesis of APPs (Bevan and Raynes 1991) and, in a mouse model, completely prevented SAA induction, showing that IL-1 is required for SAA synthesis (Grehan et al. 1997). The hepatocyte makes a significant contribution to plasma IL-1ra (Gabay et al. 2001) and would thus be an autocrine regulatory response. The liver makes this IL-1ra in response to IL-6 whereas IL-1ra from other tissue appears to be independent of IL-6 (Gabay et al. 2001).

TNFα has an ability to induce responses in vitro and would clearly do so indirectly in vivo. Transforming growth factor β (TGFβ) and interferon-α and -γ have been demonstrated to have some ability to induce APPs (Ramadori et al. 1988; Mackiewicz et al. 1990). Other factors with an influence are hepatocyte growth factor and retinoic acid (Koj et al. 1995). Insulin has a downregulatory effect on APP synthesis (Campos and Baumann 1992).

It has recently been found that a member of the IL-10 family of cytokines, IL-22, has the ability to induce an APR in hepatocytes. This cytokine, produced mainly by T cells, can interact with IL-22 receptor together with IL-10R2 to induce STAT1 and STAT3 and hence induce a range of proteins such as SAA, haptoglobin, and antichymotrypsin (Dumoutier et al. 2000a, 2000b). As yet the extent of IL-22 contribution to the APR is not known. The effects of IL-22 are also not restricted to the hepatocyte because it has been shown that epithelial cells can also respond and IL-22 may thus have pleiotropic effects. These and the APR induction are antagonized by a soluble receptor which acts as a binding protein or by receptor antagonism (Dumoutier et al. 2001; Wei et al. 2003).

Effects of nutrient deficiency or modulation

Protein synthesis by hepatocytes represents a considerable drain on amino acid precursors and total hepatic protein synthesis during inflammation. It might be expected that it would therefore be absent or greatly reduced in nutritional deficiency. However, this appears not to be the case, because in severe protein malnutrition the APR is often seen in equal or higher levels compared with individuals with normal weight for height, although such studies do not take into account a reduced resistance to infection in such individuals. In fact, when faced with an equivalent stimulus in human studies there is a reduction in response in malnutrition following, for example, immunization protocols (Doherty et al. 1993) or in animal studies (Jennings et al. 1992; Lyoumi et al. 1998). Nevertheless the response is still a strong one and is essentially maintained. The reduction is probably at the level of cytokine production rather than hepatocyte response because serum IL-6 was reduced as well as APPs (Doherty et al. 1994). This provides further evidence for the essential role of the APR and APPs in homeostasis or resistance to infection. It is often assumed that the concentration of the APPs is dependent on the rate of synthesis; however, there is evidence that the rate of clearance may be different in protein malnutrition (Morlese et al. 1998). It is also clear that certain proteins such as fibrinogen may be more severely affected by protein malnutrition than others (Morlese et al. 1998) and that the malnutrition itself, in the absence of other stimuli, may in some cases cause an increase in certain proteins (Lyoumi et al. 1998). The effects of other forms of nutritional deficiency on the APR are less well characterized, although in the reverse direction the APR can certainly alter micronutrient availability (see later, under Micronutrient changes). Low levels of vitamin E may lead to a more pronounced inflammatory response, perhaps because of a reduced ability to control oxidants.

Another factor that can modulate APRs through their effect on cytokine production is the amount of *n*-3 and *n*-6 polyunsaturated fatty acids in the diet. Fish oils that are rich in *n*-3 fatty acids reduce the proinflammatory cytokine production of IL-1 and TNFα in comparison with *n*-6 fatty acids, which increase cytokine responses (Calder and Grimble 2002). The effect of the *n*-3-rich oils is sufficient to improve the status of patients with diseases with inflammatory pathology such as rheumatoid arthritis and psoriasis or asthma and in animal studies with LPS (Calder and Grimble 2002)

Induction of other aspects of the APR

Fever has been shown to be induced by administration of proinflammatory cytokines (called endogenous pyrogens) but appears to need IL-6, which acts downstream of the potent pyrogens IL-1α or IL-1β. When the cytokines reach the central nervous system they generate prostaglandins, particularly PGE_2 in the organum vasculosum of the lamina terminalis, which reset the

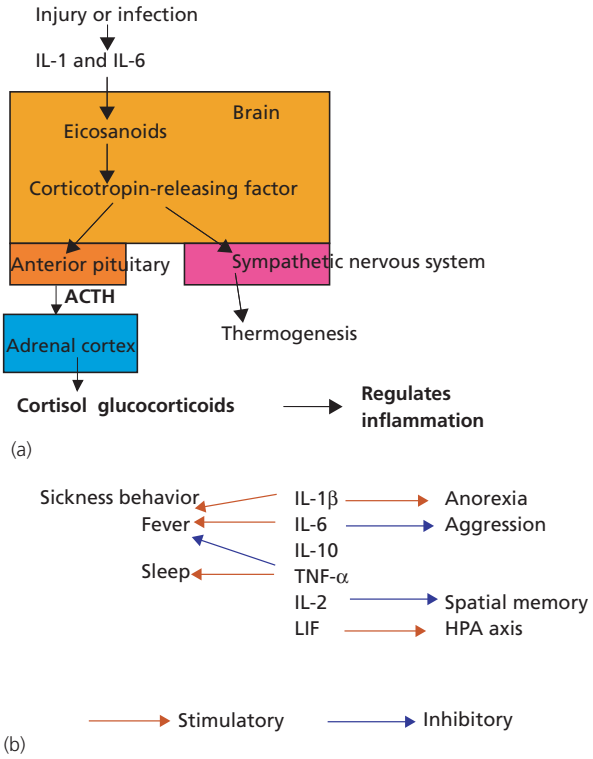

Figure 4 *Induction of fever and glucocorticoid downregulation of inflammation through brain responses to proinflammatory cytokines. HPA, hypothalamo–pituitary–adrenal; IL, interleukin; LIF, leukemia inhibitory factor; TNF, tumor necrosis factor.*

temperature set point (Figure 4a). Mice lacking the prostaglandin receptor EP_3 are unable to generate a febrile response (Ushikubi et al. 1998). Although other pathways may ultimately also act, they all generate a response in the thermoregulatory center in the anterior hypothalamus. Although the original model suggests that the cytokine originates from the periphery, there are several possible pathways and local cytokine synthesis is likely. It is even possible that endotoxins may act directly in a similar way to that proposed for hepatocyte responses. Responses have been linked to a number of different cytokines using inhibition or addition experiments, but direct effects are difficult to demonstrate. The use of knock-out mice has suggested that IL-6 and IL-1β are involved in the induction of fever (Zheng et al. 1995; Kluger et al. 1998; Netea et al. 2000; Inui 2001) whereas others such as TNFα or IL-10 appear to reduce fever (Leon et al. 1997; Leon 2002). Recently it was shown that vagotomy reduces the extent of fever in response to intra-abdominal IL-1 (Watkins et al. 1995). The sensory input of afferent vagal nerves can thus alter fever responses in the brain and this is dependent on the site and type of stimulation. The interaction between neural and immune inflammation was recently reviewed (Tracy 2002).

Studies using knock-out mice also suggest that anorexia and somnolence are regulated by IL-1β and IL-6 (Figure 4b, reviewed in Inui 2001). IL-1 appears to be important for anorexia and TNFα is thought to be needed for sleep responses. Lethargy may be caused by IL-1 because mice lacking type I IL-1 receptor do not show lethargy responses and these responses do not require IL-6 (Leon et al. 1997).

Little information is available on the proinflammatory cytokine regulation of hemopoiesis and they are likely to work through growth factors (see later under Hemopoietic responses). Thrombocytosis is regulated by IL-6 mainly through thrombopoietin (Kaser et al. 2001).

ACUTE PHASE PROTEINS

Acute phase proteins have many different functions and in this review have been organized into functionally related groups, although there is some doubt about the role of many proteins and to which category they should belong. It should be remembered that there is no requirement that a particular protein should only have one function. The choice of whether to include proteins that are made mainly outside the liver or in nonhepatic cells, or when to start considering proteins as part of the acute phase, is a difficult one. In some respects a review of the acute phase should consider TNFα and other cytokines released as early components of this system. However, this review focuses a few hours after the initial stimulus and includes proteins that are increased by at least 25 percent or more during inflammation and that are at least, in part, made in hepatocytes. Also included are proteins that show substantial increases in concentration in human sera and/or increases in several other species, which may be made in other cells that might be used to follow inflammation. It has been shown recently, using oligonucleotide array hybridization, that 7 percent of hepatic genes were responsive to LPS (Yoo and Desiderio 2003), demonstrating the importance of this response in liver function and confirming the impression that many such genes are related to host defense and immunity, metabolism, or coagulation.

Acute phase proteins are produced at a time when the host might be expected to require a downregulatory force on the systemic inflammation that generated the APR. Thus many of the proteins are thought to have an anti-inflammatory function (Tilg et al. 1997). It is interesting that, although similar proteins are found in most species, there is considerable variation between the concentrations of the proteins, and variations between which are strongly or weakly induced, e.g. CRP, haptoglobin, AGP, and α_2-macroglobulin, have very different patterns of expression in humans, mice, rabbits, and rats.

In general APPs are well conserved and many have ancestors in teleosts and elasmobranchs (Bayne and Gerwick 2001). There are some human APP deficiencies

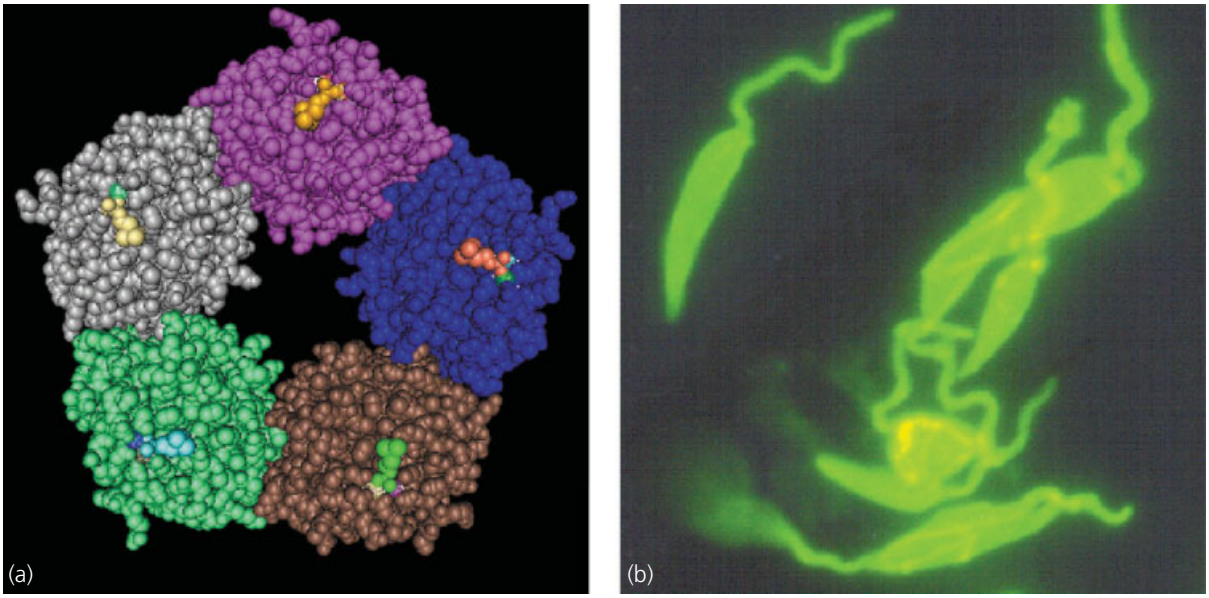

Figure 5 (a) *Structure of C-reactive protein (CRP);* **(b)** *binding of CRP to* Leishmania mexicana *demonstrated by immunofluorescence.*

which have provided information about function and knock-out mice have also provided information. APPs will now be considered according to groups with related function.

Innate immune proteins

C-REACTIVE PROTEIN AND OTHER PENTRAXINS

C-reactive protein was originally discovered over 70 years ago and given its name because it interacted with the phosphorylcholine-containing polysaccharide and lipoteichoic acid found on *Streptococcus pneumoniae* (Tillet and Francis 1930). CRP is the best known of the APPs because it is regularly used as a marker of systemic inflammation in clinical settings and can increase from approximately 1 μg/ml to 500 μg/ml in severe inflammation (see later under Clinical use of APPs and inflammation markers). The protein is, however, a member of a family of proteins (pentraxins) that includes homologs of similar size to CRP such as serum amyloid P (SAP) component or homologous domains found as part of larger proteins such as long pentraxins (PTX3). Other species usually show either SAP or CRP to be an APP. In mice, for example, CRP is present at low levels and SAP is a major APP whereas human SAP concentrations change little in inflammation (Pepys and Baltz 1983). CRPs are found in arthropods that lack an acquired immune system and often several copies are found; in the horseshoe crab these have different binding specificities (Iwaki et al. 1999). Human PTX3 demonstrates small increases in concentration during the acute phase (Muller et al. 2001b).

The common feature of these proteins is their structure which is pentameric (see Figure 5a). Crystal structures are now available for both CRP and its homolog SAP (Emsley et al. 1994; Shrive et al. 1996). They both possess the ability to bind to phosphorylated ligands such as phosphorylcholine or phosphorylethanolamine in a calcium-dependent manner. However, this is not the only ligand because phosphorylated carbohydrates can also bind (Culley et al. 2000). Such ligands are found on microorganisms including *Leishmania* spp. (see Figure 5b) One feature of these interactions is that the avidity of CRP for monomeric ligand is usually low and, only when such ligands are expressed as an array, e.g. on the surface of a microorganism, are high avidities generated. The binding specificity of SAP includes heparin, a 4,6-cyclic acetal of pyruvate, 6-phosphorylated mannose, and 3-sulfated saccharides (Hind et al. 1984; Loveless et al. 1992). CRP, SAP, and PTX3 have all been shown to interact with apoptotic cells (Gershov et al. 2000; Rovere et al. 2000; reviewed in Nauta et al. 2003). The mechanism of binding for CRP may be related to binding to damaged membranes which has been observed in a number of other systems where membrane integrity or composition is altered (Li et al. 1994).

It is clear that CRP can activate complement through the classical pathway but it has been shown that CRP activates the pathway only as far as C5 (Mold et al. 1984). The C1q binding site is found on the opposite face to the phosphorylcholine- or calcium-dependent ligand-binding face. CRP can directly interact with cellular receptors such as FcγRI (Marnell et al. 1995; Bodman-Smith et al. 2002) and perhaps also FcγRII. The result of CRP interaction with a range of micro-

organisms is increased phagocytosis by cells such as macrophages and neutrophils, either directly or indirectly through complement. These ligands on infectious organisms may allow CRP to be protective against disease as in the case of *Streptococcus pneumoniae* (Yother et al. 1982; Du Clos and Mold 2001), but may not always be so in cases of *Leishmania donovani* when CRP binding to lipophosphoglycan on the parasite increases access to the macrophage as an important part of its life cycle (Culley et al. 1996). There is little or no evidence for opsonization of microorganisms through SAP binding, although recently it has been suggested that SAP can cause phagocytosis of its ligand zymosan through murine Fc receptors (Mold et al. 2001).

The role of slightly higher baseline CRP concentrations as a predictor of heart disease is a fascinating new observation (Haverkate et al. 1997; Libby et al. 2002). It is currently important to discover whether this is a causal observation or merely a marker of some other inflammation-driven cause of atherosclerosis. A potential mechanism may be through low-density lipoprotein (LDL) uptake into monocytes or through activation of endothelial (CRP induces tissue factor) or other cell types at the lesion site.

PTX3 lacks the ability to bind to phosphorylcholine ligand but retains an affinity for carbohydrate and also binds to macrophages and can protect against fungal infection (Garlanda et al. 2002).

COMPLEMENT COMPONENTS

A number of the complement cascade proteins are APPs including the central component C3. The complement cascade acts as an innate immune and acquired immune pathway, being triggered by both antibody and the innate proteins mannose-binding lectin (MBL) and ficolin. The alternative pathway is activated by charged surfaces often presented by microbes. MBL is itself an APP (Ezekovitz et al. 1988). The complement components (see Complement) that are induced are C1q, C3, C4, C9, factor B, C1 inhibitor, and C4-binding protein. Some of these are required to replenish protein depleted by activation and usage of complement as is observed after, for example, a severe burn injury. APPs such as C4-binding protein are required as controlling proteins.

Mannose-binding lectin is a member of a family of collectins that all bind to carbohydrate on pathogens and direct these pathogens for opsonization through complement after association with a protease called mannose-binding protein-associated serine protease (MASP), which activates C1q (Matsushita and Fujita 1992). This protein is a decamer of units that have globular lectin domains and collagenous tails (Figure 6) (Peterson et al. 2001). The binding to a variety of carbohydrate structures such as mannose or *N*-acetylglucosamine on microbes can lead to phagocytosis. Besides activating complement a direct receptor for MBL has been implicated but not defined as yet. A fairly common mutation in one of the alleles leads to large reduction in secreted active protein and such individuals are more at risk of certain infections, particularly at the ages of 2–4 years before an appropriate humoral immunity has been attained (Sumiya et al. 1991). MBL is one of a number of proteins that can lead to improved presentation to T cells (Figure 7).

LIPOPOLYSACCHARIDE-BINDING PROTEIN

Lipopolysaccharide-binding protein (LBP) is found constitutively at about 5–10 μg/ml but can increase 10-fold during severe inflammation. LBP has been shown to bind to LPS and transfer it to CD14 and TLR4, and consistent with this LBP can increase the activity of LPS to activate $CD14^+$ cells by more than 100-fold (Schumann et al. 1990). However, LBP also transfers LPS into high-density lipoprotein (HDL) within which environment LPS is almost completely without activating effect (Wurfel et al. 1994). As the LBP interacts mainly with the lipid A portion of the LPS, it is unlikely to bind directly to bacteria and opsonize them. Further information of its role comes from LBP-deficient mice which can clear LPS normally but need LBP for an inflammatory response to LPS. Furthermore, these mice are more susceptible to intraperitoneal salmonella infection (Jack et al. 1997). In the *salmonella* infections, TNFα synthesis was reduced and evidence was presented that LBP contributed towards TNFα activation of polymorphs (Fierer et al. 2002).

SECRETORY PHOSPHOLIPASE A_2

Phospholipase A_2 (PLA_2) is an enzyme that generates fatty acid and a lysophospholipid from phospholipid. The enzyme exists in a cytosolic form and as a secreted version ($sPLA_2$), and there are several different isoforms of each. The products are important for signaling pathways and generation of lipid inflammatory mediators and for this reason have been considered as potential targets for anti-inflammatory drugs. The secreted PLA_2 is an APP (Andreani et al. 2000), of which the most studied form, $sPLA_2$ type IIA, is a potent anti-streptococcal and anti-staphylococcal enzyme (Weinrauch et al. 1998). It is also thought to be coordinated with other prostaglandin synthesis enzymes in order to play a role in inflammation. The effects and potential functions of such enzymes are clearly wide ranging and a range of different receptors is being characterized (reviewed in Lambeau and Lazdunski 1999; Murakami et al. 2000).

Protease inhibitors

There are a number of protease inhibitors present in plasma that have a spectrum of activity and many of

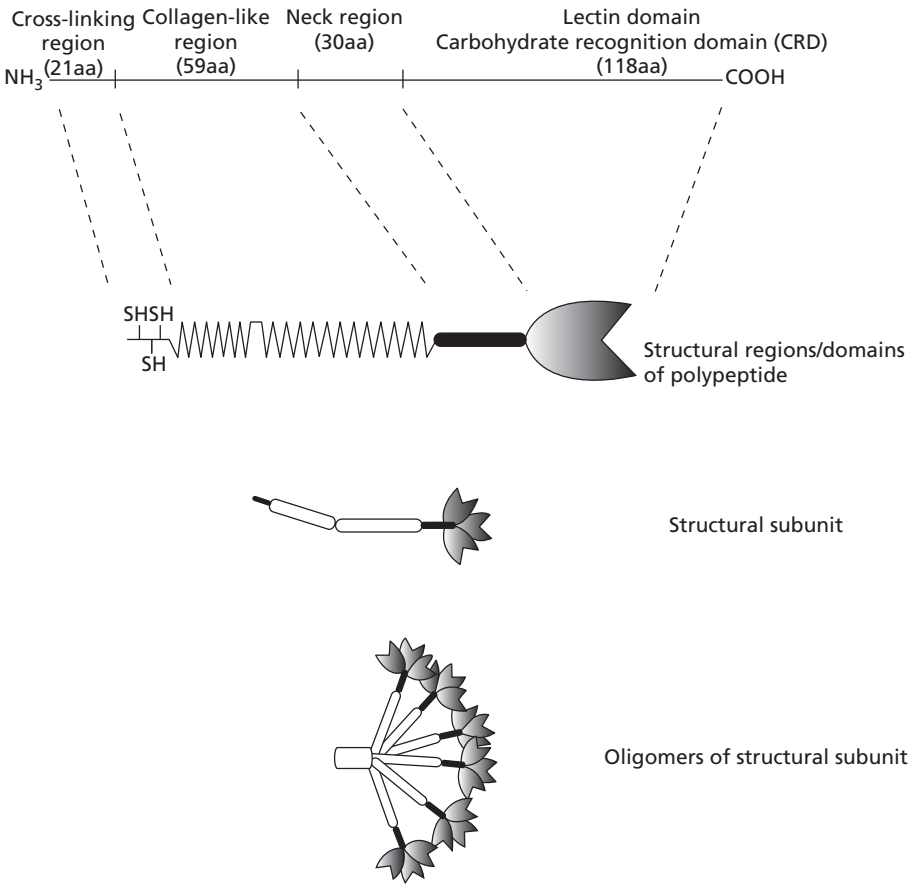

Figure 6 *Structure of mannan-binding lectin (MBL) showing structural domains, subunits, and oligomeric organization. (Redrawn from Peterson et al. 2001.)*

which increase in response to inflammation. They generally increase at later time points (2–5 days). Names of the protease inhibitors have often been given on the basis of the protease that allows demonstration of inhibitory activity rather than the actual protease that they inhibit in vivo. Although a major role is to inhibit endogenous proteases and thus control inflammation and tissue clearance before remodeling, it has also been proposed that some functions may relate to control of microbial proteases (Hiemstra 2002). Many of these protease inhibitors are serine protease inhibitors of a family called serpins. Some of these inhibitors have particular functions such as plasminogen activator inhibitor, antithrombin III, and C1q inhibitor which are therefore considered in other sections.

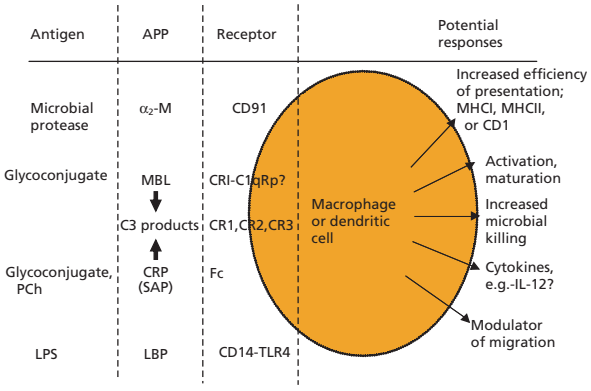

Figure 7 *Diagram depicting the different acute phase proteins that deliver particular microbial products to macrophages or dendritic cells. This can have a number of different potential outcomes, all of which have been described for at least one of the uptake pathways.*

α_1-ANTITRYPSIN OR α_1-PROTEASE INHIBITOR

α_1-Protease inhibitor (α_1-PI) is defined as a serpin because it is structurally related to members of a family of serine protease inhibitors. Already present at approximately 2–3 mg/ml it can increase fourfold. The name α_1-PI is to be preferred to antitrypsin because its actual antiprotease effect is more likely to be on neutrophil elastase and cathepsin G or protease 3. This glycoprotein is synthesized mainly by hepatocytes but also by macrophages and neutrophils. Occasionally we can learn about function from deficiency diseases and this is the case for α_1-PI (Carrell and Lomas 2002). The disease leads to a greatly increased risk of emphysema or liver disease. The

emphysema is the result of the lack of control of proteases, and the liver disease also caused by a problem with misfolding and protein aggregates accumulating in the hepatocyte endoplasmic reticulum (Lomas et al. 1992). Thus, a major function of this protein is to prevent degradation of elastase in the lung. Treatment with replacement α_1-PI was able to reduce frequency of lung infection in α_1-PI-deficient patients (Lieberman 2000). After complex formation with protease, a large change in the protease structure is generated (Huntington et al. 2000) and clearance follows by endocytosis through the serpin enzyme complex (SEC) receptor (Perlmutter et al. 1990; Joslin et al. 1992).

α_1-ANTICHYMOTRYPSIN

This protein is increased to a greater extent (up to sixfold) than other slow responding human APPs such as α_1-PI (see Figure 1b). Again, the specificity for serine proteases and localization is such that it is more likely to inhibit cathepsin G and mast cell chymases. Interestingly a point mutation in α_1-antichymotrypsin (α_1-ACT) can lead to reduced concentrations in plasma and a deficiency disease similar to that seen with α_1-PI. This is only seen with particular mutations (Faber et al. 1993). As with other serpinopathies (of C1 inhibitor or antithrombin III) many α_1-ACT mutations do not lead to such pathology. This is likely to be because they are produced at 10 percent of the rate and degradative pathways can handle the inappropriately folded protein. Interestingly, the presence of an APR may precipitate pathology when the rate of synthesis is increased, although this is based on a limited number of observations.

α_2-MACROGLOBULIN

This is a very large protein with an interesting mechanism of inhibition. It is so large that it can be visualized by electron microscopy and it acts to trap the protease when the protease cleaves a bond on the internal aspect of one of the faces of the protein. The change in conformation of the α_2-macroglobulin reveals a site for interaction with a receptor called LDL receptor-related protein or CD91 (Moestrup and Gliemann 1989) (see Figure 8). CD91 has been identified as a receptor site for heat shock protein (HSP)-mediated binding and endocytosis. The result of this is that α_2-macroglobulin may also be an immune component because it improves adjuvanticity through cross-presentation (Binder et al. 2001) (see Figure 7).

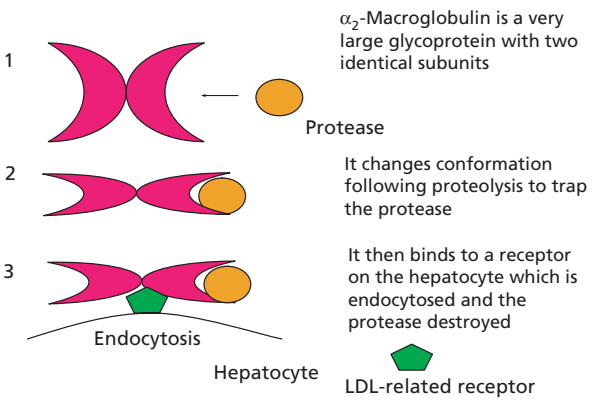

Figure 8 *Diagram depicting the mechanism by which α_2-macroglobulin captures proteases and delivers them from endocytosis into macrophages and other cells expressing CD91 or low-density lipoprotein (LDL)-related receptor.*

Transport proteins

FERRITIN

Ferritin is composed of two sorts of protein subunit – H and L – which combine together to form a complex of 24 subunits that form an apoferritin shell which can hold up to 4500 iron atoms. It is present inside the cell and acts mainly as a storage protein rather than a transporter, but smaller amounts are also found in the serum. The serum form is thought to be derived from the L subunit and is normally poor in iron. Hepatocyte cytoplasmic ferritin is also predominantly the L form. Its primary function is to sequester iron and, by reducing availability for microbial growth, this helps control infection. However, ferritin should be considered as a member of a group of proteins that together with transferrin and transferrin receptor work to make available the iron necessary for many of the host of mammalian iron-containing proteins. Ferritin synthesis is induced in a post-transcriptional way by intracellular iron availability. It is also induced by proinflammatory cytokines in a complex way which also involves increased secretion (Torti and Torti 2002), although IL-4 and IL-13 may also regulate ferritin produced in macrophages (Weiss et al. 1997). The function and regulation of iron availability appear to be linked with another APP called hepcidin which is produced by hepatocytes and macrophages (Nemeth et al. 2003)

HAPTOGLOBIN

This glycoprotein is mainly synthesized in hepatocytes but some is also made in other cell types. Its function appears to be to bind to free hemoglobin and prevent damage, particularly renal damage, which would be caused by free hemoglobin, and then to recycle the iron and reduce availability for microbes. There are two alleles (designated 1 and 2) which give rise to polymeric molecules with properties that diverge considerably (Langlois and Delanghe 1996). Allelic associations exist with infections, atherosclerosis, and autoimmune disease. The haptoglobin and hemoglobin complex interacts with a receptor recently identified as CD163 (Kristiansen et al. 2001) which clears the iron mainly to macrophages. However, the haptoglobin-deficient mouse shows no

major symptoms until placed under strong hemolytic stress, when it displays renal injury as a result of oxidative damage (Lim et al. 1998). Extrahepatic synthesis in lung macrophages may hint at other functions.

HEMOPEXIN

Hemopexin has the ability to bind heme released from hemoglobin or other heme-containing proteins, thus acting as a second-line defense against hemoglobin damage. As for haptoglobin, this reduces the opportunity for free iron to cause oxidative damage and also reduces the ease with which microorganisms can have access to iron for growth. It has been proposed that, once heme has been bound with high affinity (dissociation constant $K_d < 1$ pmol/l), a site is revealed that allows binding to a hepatocyte receptor; however, it is unclear if this is responsible for the total uptake by hepatocytes (Noyer et al. 1998). Heme would then be catabolized to bilirubin, biliverdin, and iron, with hemopexin and the receptor recirculating. Deletion of the gene for hemopexin generated mice that had normal handling of iron under unchallenged conditions, but the mice were less able to cope with hemolysis (Tolosano et al. 1999). Although haptoglobin- and hemopexin-deficient mice have increased amounts of the other protein (perhaps to compensate) the double knock-out has a similar phenotype to the single knock-outs. The delivery of heme to cells for destruction is part of a system that includes heme oxygenase which acts to reduce oxidative stress from iron inside the cell (see later, under Liver protective responses).

GC GLOBULIN

Group-specific component (Gc globulin), also known as vitamin D-binding protein, is only a very minor acute phase reactant. Its function appears to be twofold: it acts in clearing actin, a protein that has been implicated in the formation of microthrombi (Lee and Galbraith 1992). Increased tissue damage releases large amounts of actin that need to be cleared, and this first function is achieved in conjunction with the muscle cell-derived gelsolin. Initially after trauma, levels are reduced, presumably reflecting functional depletion and subsequently rise following IL-6 effects on hepatocytes. A second function, as its other name suggests, is as a transporter of vitamin D_3 and its major metabolites including the active 1α,25-dihydroxyvitamin D_3 (Daiger et al. 1975). When circulating, only a small percentage of the circulating protein has vitamin D bound; nevertheless it appears to control availability and uptake by cells. Other reports have suggested an immunomodulating function.

Procoagulant/fibrinolytic proteins

In the acute phase, the balance between the different factors that promote or clear clot formation is one that shifts towards the procoagulant. The process of coagulation is linked to inflammation because coagulation increases inflammation and inhibition of this coagulation can reduce the severity of inflammation which involves coagulation. In addition to the proteins mentioned below, factor VIII and von Willebrand factor are APPs induced by IL-6.

FIBRINOGEN

A range of different mutations in humans has led to rare afibrinogenemias where complete lack of fibrinogen is associated with bleeding disorders. Alternately less severe dysfibrinogenemias have different presentations and patterns of pathology. Fibrinogen is composed of two sets of three different sorts of chains – lack of any one of these leads to deficiency (Doolittle 1984). As well as being an important protein for blood clot formation with the platelet plug, it has a role in inflammation, wound healing, cell migration, and cell proliferation. These properties are thought to be related to interactions with integrins on endothelial cells or (CD11b/CD18) on leukocytes.

This protein is required for wound healing and appropriate cell distribution and migration during the wound healing process (Drew et al. 2001), which was studied in knock-out mice. Although mainly synthesized in the liver, extrahepatic synthesis occurs, e.g. in lung epithelial cells.

PLASMINOGEN AND PLASMINOGEN ACTIVATOR

This protein is a zymogen that is cleaved by the plasminogen activators – urokinase (uPA) or tissue type (tPA) – to form plasmin, an enzyme that cleaves fibrin and other extracellular proteins to remove clots. Upregulation of both plasminogen and plasminogen activator and the variety of other coagulation/fibrinolysis proteins does not necessarily favor enhanced thrombosis (Esmon 2000), but may rather represent a replacement of consumed protein.

PROTEIN S

Activated protein C and protein S work together as an anticoagulant and an anti-inflammatory agent. When small microthombi of fibrin and thrombin are deposited in inflammation or infection then thrombin/thrombomodulin activates the protein C (an antithrombotic serine protease). This led to a trial in patients with severe sepsis of an activated protein C that showed a small improvement in mortality from sepsis compared with placebo, a rare finding because many attempts to improve outcome in sepsis have failed (Bernard et al. 2001; see also Shock/sepsis). Further studies are needed to confirm efficacy.

VITRONECTIN AND PLASMINOGEN ACTIVATOR INHIBITOR TYPE I

Although mostly synthesized in the liver, mRNA for vitronectin is found at lower levels in the brain, heart, and adipose tissues. It is stimulated by IL-6 and protein can increase by two- to threefold (Seiffert et al. 1994). Vitronectin is a multifunctional adhesive glycoprotein that forms a complex with plasminogen activator inhibitor type I (PAI-1), which stabilizes the function of the latter. PAI-1 binds to plasminogen activators such as tPA to generate a stable inactive complex. Vitronectin also helps PAI-1 binding to fibrin. In addition PAI-1 acts as an antiadhesive factor for cell adhesion involving vitronectin and integrins or the urokinase receptor. PAI-1 deficiency in humans is associated with bleeding disorders, indicating a role in stable clot formation.

ANTITHROMBIN III

Antithrombin II is a negative APP, which by its reduction leads to a more procoagulant state. Antithrombin III-deficiency diseases are characterized by thromboembolism (Mackie et al. 1978). It is a serpin that inhibits thrombin and other proteases that cause coagulation.

Regulatory molecules released into the circulation during the APR

IL-1 RECEPTOR ANTAGONIST

The IL-1Ra, as its name implies, prevents IL-1 action by competing for available receptor. Originally found as a cytokine generated by the same cells that make the active form, but temporarily delayed in response, it has more recently been described as an APP under different regulation in hepatocytes (Gabay et al. 2001).

MACROPHAGE MIGRATION INHIBITORY FACTOR

With the similarity of migration inhibitory factor (MIF) to procalcitonin, it appears that MIF acts as an APP in septic or immune inflammation rather than trauma-induced inflammation (Beishuizen et al. 2001). MIF is an interesting protein which appears to have many immune and inflammation-related functions. Its function may relate to reducing glucocorticoid effects on the inflammatory response (Baugh and Bucala 2002). It appears to mediate shock responses in reaction to Gram-positive and -negative bacteria, and mice that lack MIF are resistant to LPS-induced shock (Bozza et al. 1999). The mechanism of action of MIF remains somewhat unclear despite existing in large extracellular amounts, and no cellular membrane receptor has been identified. It is also found intracellularly and an intracellular ligand, Jab1, has been linked to some responses (Kleemann et al. 2000).

SOLUBLE ADHESION MOLECULES

Soluble intercellular adhesion molecule (sICAM) or soluble vascular cell adhesion molecule (svCAM), which are immunoglobulin adhesion molecule family members, and soluble E selectin are all found in increased amounts in plasma after any infectious and inflammatory stimuli that give rise to systemic effects (Kulander et al. 2001; Reinhart et al. 2002). Their function may relate to an ability to inhibit cellular extravasation.

ANGIOTENSINOGEN

Angiotensinogen is largely produced in the liver, although other tissues can make it and it is cleaved by renin to angiotensin II, which is a powerful vasoconstrictor that controls salt and water homeostasis (Morgan et al. 1996). Other studies have suggested that it may also have proinflammatory effects on vascular endothelia (Brasier et al. 2002).

Other APPs of uncertain function

SERUM AMYLOID A

Serum amyloid A (SAA) protein is a major APP in humans but it is unclear what the true function for this protein might be. SAA was first discovered as the serum component precursor of amyloid AA (Rosenthal et al. 1976). Since then several members of the family have been found. Human SAA is a gene family including two acute phase forms, SAA1 and SAA2, as well as a constitutive form SAA4 (Uhlar and Whitehead 1999). During normal conditions the most abundant isoform is SAA4, but during severe inflammation this protein increases only slightly with the major forms becoming SAA2 and particularly SAA1 which can increase 1000-fold up to 500 μg/ml. All forms of the protein are found associated with HDL to which it is reversibly bound (more than 95 percent in complexed form). This association with HDL has led to the idea that SAA function might be linked to that of HDL. When SAA associates with HDL other lipoproteins such as apolipoprotein A1 are displaced (Coetzee et al. 1986). Nevertheless, despite the demonstration that SAA has effects on lipid transport between HDL and various cells and effects on enzyme activities, no clear role has been demonstrated. Changes in lipid metabolism are relatively small and perhaps to be expected from any protein that displaces other proteins and becomes a major protein (up to 50 percent or more) in the total HDL protein in severe inflammation. In vivo cholesterol transport was not altered by SAA1 overexpressed through an adenoviral construct, although the constitutive form did alter lipoprotein profiles (Kindy et al. 2000).

An alternate hypothesis for SAA function is that it is involved in immune function as a chemotactic agent. Evidence for this has been gathered from experiments

that show movement of a variety of cells in response to lipid-free SAA (Xu et al. 1995). As further support for this, interaction with a G-protein-coupled receptor FPRL1 has been suggested (Su et al. 1999). Surprisingly HDL inhibits this function and, if this is a major function, it is unclear why hepatocytes would make so much SAA. An interaction with the RAGE receptor has also been suggested for the amyloidogenic form of SAA (Yan et al. 2000).

SAA3 is synthesized extrahepatically in a number of cells such as macrophages and adipose cells (Meek and Benditt 1986). It has recently been demonstrated that adipose cells synthesize SAA3 in response to hyperglycemia (Lin et al. 2001). In addition epithelial tissues were found to express SAA1, SAA2, and SAA4 under normal physiological states (Urieli-Shoval et al. 1998).

α_1-ACID GLYCOPROTEIN

Acid glycoprotein (AGP) (also called orosomucoid) is highly acidic with a p*I* of between 2.8 and 3.8 as a result of approximately 60 percent of its mass being made up of N-linked glycans (Fournier et al. 2000). It is a member of a class of protein called the lipocalins, which also includes α_1-microglobulin and retinol-binding protein. In plasma it is an abundant protein (see Table 1), which can increase up to fivefold from 0.3 to 0.6 mg/ml.

A large proportion of the research on this protein is related to its ability to bind and alter the bioavailability of a wide range of drugs. This is because a number of sites are available to interact with drugs of both basic and neutral lipophilic character and even acidic drugs. Some of the more important drugs bound are propranolol, verapamil, and quinine (Israili and Dayton 2001). The fact that AGP increases severalfold during an APR may thus alter the availability of drug and pharmacokinetics in the acute phase as compared with the normal dosage of drug (e.g. quinine). This ability to carry small molecules may be part of AGP's function and certainly AGP can be seen to be associated with steroid hormones such as progesterone. However, several other possible functions exist. The N-linked sugars themselves change during the APR becoming shorter, whereas in pregnancy they are found to be longer, perhaps reflecting the rate of synthesis (Raynes 1982). The glycosyl transferases responsible for full glycosylation of proteins are also induced by cytokines, but their induction takes place over a slow time course (Mackiewicz et al. 1987). This phenomenon is not restricted to AGP. A further change to the carbohydrate that depends on activation status of secreting cells is the presence of a sialyl Lewis X structure on a percentage of AGP glycans, although this too is not restricted to AGP (De Graaf et al. 1993). It is possible that this acts to inhibit selectin-mediated effects at the endothelium. An immunomodulating capacity has been reported; however, this is still contentious and, although AGP is reported to prevent TNFα or LPS septic shock under some circumstances, this is not always observed in different models. Other reported observations include an inhibition of lymphocyte proliferation and a selective alteration in permeability of endothelia.

One alternative possibility that is attractive and for which there is limited evidence is that it may act to bind and inactivate pathogens that would use such N-linked glycans to bind to endothelia or gain entry to cells, e.g. a nonspecific resistance to infections such as that with *Klebsiella pneumoniae* (Hochepied et al. 2000). This may be related to the property of certain pathogen adhesins to bind to N-linked sugars.

CERULOPLASMIN

This protein is named after its blue color as a result of the copper it contains. It requires the copper for function but is not involved in transport of this metal despite the fact that it contains the bulk of plasma copper. Rather it has ferroxidase activity and is involved in the release of iron from stores. This property came to light following the discovery of a neurodegenerative deficiency disease (aceruloplasminemia) (Yoshida et al. 1995; Hellman and Gitlin 2002).

Negative APPs

There is no obvious reason why a protein such as albumin should be reduced in the APR; nevertheless this process is a controlled one in which the synthesis rate is reduced. This active downregulation is through transcriptional and post-transcriptional control (Perlmutter et al. 1986). The most plausible reason for this is that, although there is an overall increase in protein synthesis rate by the hepatocyte during the APR, the required switch towards the upregulated proteins requires extra capacity which can be achieved only by downregulating synthesis of this major serum protein.

Transthyretin was previously called prealbumin and functions to transport retinol-binding protein and thyroxine. Transferrin transports iron but it is reduced in the acute phase, presumably to reduce availability of iron for microorganisms that usually have a greater affinity for the iron it carries. The transferrin receptor is responsible for uptake into those tissues that require the iron.

Liver protective responses

Following inflammatory stimulation the hepatocyte also starts to produce a number of other enzymes and proteins that have host-protective function. Inducible nitric oxide synthase (iNOS) was first identified in hepatocytes and has an ability to protect the hepatocyte against injury in severe sepsis. Raised plasma nitric

oxide is observed in a number of inflammatory conditions. Another enzyme produced in hepatocytes, as well as other cells such as endothelial cells, is heme oxygenase which has been demonstrated to have a protective role against stress from oxidative conditions and to reduce inflammation (Willis et al. 1996). This enzyme is responsible for reducing the effects of iron released from heme-containing enzymes (Ferris et al. 1999). Its main role may lie in protecting not only hepatocytes but also endothelial cells from injury.

Metallothionein is an intracellular low-molecular-weight protein that appears to have several functions, including protection against heavy metal and oxidant damage, or metabolism and control of zinc (Coyle et al. 2002). Two isoforms are induced in hepatocytes in response to IL-6, as well as other stimuli such as metals or drugs. An increase in zinc content in hepatocytes is mirrored by a hypozincemia.

Clinical use of APPs and inflammation markers

The most commonly used marker of APR has traditionally been the erythrocyte sedimentation rate (ESR), which is simple to perform but suffers from problems that affect results, such as anemia, and an increase with age. It has been considered that the major factor behind the ESR is the concentration of fibrinogen, which is slower to react than some of the faster APPs. Mainly for these reasons and the increase in sensitivity of assays, CRP is currently the best marker of severity of inflammation. There are, however, exceptions to the rule that CRP reflects inflammation in, for example, systemic lupus erythematosus (SLE) when CRP levels are not increased (Pepys et al. 1982). As a measure of inflammation, SAA may be slightly more sensitive for particular diseases (Malle and de Beer 1996) but is more difficult to measure for a number of technical reasons, including a difficulty in generating good antibodies that are specific for the acute phase form, and do not recognize the constitutive form. Certain cytokines have been reported to have levels that correlate with severity of inflammation but in general they suffer from problems of rapid fluctuation, with the result that even the better ones, such as IL-6, are unlikely to be used in preference to CRP. In the future other markers may be used that provide more information than the current nonspecific ones, e.g. procalcitonin may be useful because it reacts faster than CRP and is induced only by infection and not by other sterile inflammatory stimuli (Chirouze et al. 2002; Reinhart et al. 2002). Alternately, proteins specific for damage to particular organs or cells have been investigated, although to date little improvement on CRP has been found either for any specific inflammatory disease or to be specific to particular cell types or locations. Neonatal tissues also appear capable of an APR and APPs can be used as markers of infection (Dollner et al. 2001).

High-sensitivity CRP assays that measure higher levels within the normal range revealed that higher CRP was a risk factor for coronary heart disease. In addition, statin therapy, which reduces coronary events, also reduces CRP (Ridker et al. 2001). Following this a number of potential markers of vascular inflammation have been examined, e.g. sICAM-1, IL-6, TNFα, and soluble P-selectin, all of which indicate an increased vascular risk in a number of clinical settings (reviewed in Blake and Ridker 2001). The APR is largely unaffected by age although baseline levels of CRP increase slightly with age. CRP has been identified at lesion sites; however, other APPs such a fibrinogen are also associated with atherosclerosis. As CRP is raised in a number of subclinical conditions, the value of such low level CRP determinations may be more than currently appreciated.

The APR may have effects on other markers used to assess, for example, nutritional status. Vitamin A measurement in serum is also somewhat confused by the fact that the carrier transthyretin and retinol-binding protein are negative APPs and thus serum carriage of vitamin A may be reduced as a result. Transferrin receptor and ferritin may be used to measure iron deficiency but transferrin receptor may have the advantage that it is not subject to the confusion caused by potential APP responses of the ferritin.

HEMOPOIETIC RESPONSES

Lymphocytes

The APR includes increases in glucocorticoids and catecholamines, which have considerable effect on the thymus causing a large increase in apoptosis (Haeryfar and Berczi 2001). This may reflect the greater importance of diverting resources to the immediate and innate immune mechanisms rather than promoting long-term adaptive immune responses.

Polymorphonuclear cells

The leukocytosis that occurs in even comparatively mild inflammatory conditions results in an increased release of cells from the bone marrow and a consequent rise in the concentration in the circulation. As the movement from the bone marrow to the circulation under the control of cytokines, such as IL-6, granulocyte–macrophage colony-stimulating factor (GM-CSF), and G-CSF and others, continues and severity of inflammation increases, less mature forms ($CD34^+$) can migrate into the circulation (Liu et al. 1997). The increase in numbers thus outweighs the disappearance of these cells into the site of inflammation or increased apoptosis rates. This

response provides rapid supplementation of cells, the function of which is to kill microorganisms. The cytokine control of release of cell type is best seen in asthma or helminth infections. IL-6-deficient mice have normal circulating neutrophil numbers but do not show leukocytosis to *Listeria monocytogenes* and are thus more susceptible to this infection (Dalrymple et al. 1995).

Other cells

Although there are no initial changes in red cell numbers after a prolonged inflammatory response resulting from autoimmune stimuli, chronic infection, or cancer, a reduced number of erythrocytes are seen in circulation which is often called the anemia of chronic disease. This results from a combination of factors such as reduced iron, removal of cells by phagocytosis, reduction in synthesis rate in bone marrow, and reduced erythropoietin, several of which are influenced by proinflammatory cytokines (Bron et al. 2001).

Circulating monocytic cells are increased during the first 24 h and this increase comes from an increased rate of release from the bone marrow, which cannot be caused by the stores of cells because there are limited supplies, but rather result from an increased cell cycle turnover. This is controlled by M-CSF as has been seen in phase I trials of M-CSF (Weiner et al. 1994).

Platelets are also increased during an inflammatory state and thrombocytosis correlates with IL-6. Thombocytosis is controlled by thrombopoietin (TPO), which is removed by platelets themselves. IL-6 does not appear directly to regulate platelet counts but rather induces TPO because IL-6 induction of platelet increases can be prevented by neutralization of TPO (Kaser et al. 2001). TPO may thus be considered an APP (Cerutti et al. 1999).

METABOLIC CHANGES

Lipid metabolism

The lipoprotein changes that occur in different species can vary, so the following references are all to humans except where indicated. One of the major changes is the hypertriglyceridemia, largely because of the increase in very-low-density lipoprotein (VLDL) through reduced clearance or increased production (Feingold et al. 1992). Driven by cytokines such as TNFα, IL-1, and IL-6, the hepatocyte increases synthesis of fatty acid which is esterified and incorporated into VLDL. At high concentrations, LPS from bacterial infection has the ability to inhibit lipoprotein lipase, an enzyme responsible for clearance of triglyceride-rich VLDL (Feingold et al. 1992). There are other changes in the VLDL during inflammation, such as an increased sphingolipid content, which also reduce clearance (Krauss et al. 1990). At the same time there is a decreased hepatic lipase and tissue expression of apolipoprotein E.

HDL and LDL are decreased during an APR whereas VLDL levels are increased. The HDL apolipoproteins apo-AI and apo-AII are both negative APPs and HDL content is decreased and replaced with other proteins such as SAA and apo-J. The role of apo-J is not known. The HDL-cholesterol is thus also reduced. The HDL that circulates is depleted in cholesterol ester but has higher free cholesterol, triglyceride, and sphingolipid (Auerbach and Parks 1989).

During an APR the anti-inflammatory and antioxidative properties of HDL are reduced. The reason for this is not entirely clear but a possible explanation is that it may be related to a decrease in content of certain enzymes such as paraoxanase or PAF acetylhydrolase (Feingold et al. 1998). Equally it may be that HDL takes up a number of inflammatory lipids or oxidized lipids released into the circulation. The cholesterol ester and total cholesterol content of acute phase HDL is lower than normal, although the reason is uncertain and the free cholesterol, triglyceride, and sphingolipid are increased.

Protein metabolism

The most obvious change that occurs dependent on proinflammatory cytokine action is muscle protein degradation, although a decreased rate of both myofibrillar and sarcoplasmic protein synthesis also contributes. There is a negative nitrogen balance that occurs in systemic inflammation which results in body weight loss. The cytokines responsible for this weight loss are thought to be TNFα, IL-1, IL-6, etc. The degradation of muscle protein provides amino acids and the hepatocyte increases amino acid uptake in order to cope with the increased protein synthesis and secretion (reviewed in Fischer et al. 1995). The synthesis of such an array of APPs is thought to give rise to a deficiency in sulfur-containing amino acids which are in particular demand (Grimble and Grimble 1998). Nevertheless, as previously indicated by the fact that the APPs are still synthesized in protein malnutrition states, APP synthesis is largely preserved. Rather the lack of these amino acids tends to affect glutathione synthesis to a greater extent (Grimble and Grimble 1998). Another amino acid of particular importance during inflammation is glutamine, which is essential for immune function in critically ill individuals (Andrews and Griffiths 2002).

Micronutrient changes

There are several levels of interaction between micronutrients and inflammation because the inflammation itself can reduce availability of micronutrients, and in

the reverse direction micronutrient deficiency may alter the severity of inflammation and the ability to generate inflammatory mediators. It is perhaps also necessary to say that assessment of micronutrient status is frequently based on blood analysis and this, as has already been shown, is heavily dependent on carrier proteins in the serum. An example of this is vitamin A which is reduced in serum during inflammation because of reduced levels of carrier protein; this must be taken into account when assessing vitamin status. The deficiency of vitamin A does, however, also lead to a more inflammatory response (Wiedermann et al. 1996) – an effect that may be the result of an alteration of cytokines and expansion of myeloid cells (Kuwata et al. 2000).

Other micronutrients affected by inflammation include the levels of zinc, iron, and copper which are all decreased by inflammation. Again many of these reductions may not reflect whole body levels but are likely to reflect available levels for peripheral or immune cells. The decrease is related to the increased production of metallothionein in the liver (Cousins and Leinart 1988). The effect of zinc depletion may have adverse effects on the immune system and may relate to a switch to a more Th2-like phenotypic response to infection (Prasad 2000). Selenium has recently been shown to be important for effective responses, particularly to viral illness (Beck and Levander 2000), and is also reduced during acute inflammation (Maehira et al. 2002); this may also be the reason for reduced glutathione through alteration in selenium availability for selenium-containing antioxidant enzymes such as glutathione peroxidase and thioredoxin reductase. Selenium deficiency appears to reduce the synthesis of a set of hepatocyte-produced proteins in rats (Fischer et al. 2001).

HORMONAL CHANGES

In inflammatory conditions, the major endocrine changes are increased plasma concentration of glucagon, glucocorticoid, and catecholamine. One of the major changes that occurs is stimulation of the hypothalamic, pituitary, and adrenal glands in an ordered manner. This occurs after cytokine stimulation and involves alteration in certain hormones and leads to the induction of the controlling glucocorticoids such as prednisolone or cortisol (see Figure 4, p. 6). Loss of mediators such as corticotropin-releasing hormone reduces but does not prevent responses (Jacobson et al. 2000). Cytokines also induce the production of corticotropin-releasing factor (CRF). This has recently been found to be important not just for its ability to generate ACTH in the pituitary and then in turn corticosteroid in the adrenal cortex, but also because it can act on immune cells and has an anti-inflammatory action on a number of immune cells that express one of the receptors for CRF (Casadevall et al. 1999). The changes in such hormones can stimulate the metabolic changes seen in infection or inflammation (Bessey et al. 1984). Although the glucocorticoids increase in the acute phase there is a reduced production of mineralocorticoids and androgens. Triiodothyronine (T3) and thyroxine (T4) are reduced during the acute phase (Woloski and Jamieson 1987). Sex steroids are also changed, with some increased and some decreased.

Immunostimulatory hormones such as prolactin, growth hormone (GH), and insulin-like growth factor 1 (IGF-1) are suppressed. The reduction in the concentrations of GH and IGF-1 or the reduction in the ability of cells to respond may be part of the reason for the protein imbalance that leads to catabolism of muscle and synthesis of APPs.

Arginine vasopressin (AVP) is stimulated by IL-6 and this causes hyponatremia by increasing water reabsorption. AVP is also synthesized within the hypothalamus in response to cytokines and acts in a synergistic way with CRF (Chikanza et al. 2000). Prolactin is synthesized in the pituitary, and both prolactin and AVP have generally proinflammatory effects (Chikanza et al. 2000). CRF also induces α-melanocyte-stimulating hormone (αMSH) in the pituitary, which is an anti-inflammatory hormone acting on several tissues.

Procalcitonin is a 13-kDa precursor of the hormone calcitonin. The gene *calc-1* gives rise to an intracellular protein that can be secreted. Following infection-induced inflammation it becomes elevated about 4 h after endotoxin administration and is back to normal after about 24 h; as previously indicated under Clinical use of APPs and inflammation markers, it may have value in that its induction appears to be specific to infectious inflammation. Under normal conditions, expression is limited to the thyroid but in sepsis all tissues and particularly parenchymal cells produce it (Muller et al. 2001a), although the reason for infection specificity is not clear. Its function is also somewhat unclear, with some reports suggesting that it may have cytokine/chemokine-like properties and others hormonal properties. It appears to reduce survival in models of systemic infection (Nylen et al. 1998).

Leptin is a hormonal protein that is synthesized in the adipocyte which at least in some circumstances appears to behave as an APP. The 16-kDa protein is similar in structure to the IL-6 family (Fantuzzi and Faggioni 2000). The leptin receptor present on target cells also has similarity to IL-6 receptors because it is a gp130-containing complex; despite this leptin has not been shown to have any ability to induce hepatic APP synthesis. The role that led to the gene's discovery in obese mice is one of lipid metabolism control. This relates to the fact that larger fat stores produce more leptin, which then regulate appetite and energy expenditure through specific areas of the brain. Conversely, when leptin is low hunger is stimulated, and this may relate to the fact that hunger is depressed during inflammatory episodes when leptin is stimulated (Faggioni et al. 2001).

However, this is not the only function because the obese leptin-deficient mice have several other defects. It has been demonstrated that immune responses are also inhibited in the absence of leptin such as reduced phagocytosis by macrophages, which leads to a impaired host defense to gram-negative pneumonia (Mancuso et al. 2002).

FEVER AND OTHER BEHAVIORAL CHANGES

The process of fever is thought to be beneficial because overall it is more harmful to the microorganism than the host and may put additional stress on the microorganism inducing, for example, heat shock proteins (Hasday et al. 2000). Some animal models support an increased resistance at higher temperature. An alternate concept is that it favors mammalian membrane function.

It is reasonable to assume that somnolence will reduce energy expenditure to allow redirection of resources to fight infection and for tissue repair. It is possible that similar arguments might also account for anorexia, because a fit host would have sufficient protein resource to survive a sufficient time to control infection.

CONTROL OF SYSTEMIC INFLAMMATION

Current new therapies designed to inhibit inflammation are often intended to have an effect at local level to control damage done to specific organs or structures as, for example, in rheumatoid arthritis. In part this research is driven by the fact that the current most powerful anti-inflammatory drugs are steroids, which have considerable metabolic side effects. It is also clear, however, that these treatments also reduce the inflammation systemically. The range of different approaches to inhibit inflammation has also increased. Recently the use of soluble TNF receptor or humanized monoclonal antibody to TNFα has been shown to be an effective treatment for rheumatoid arthritis, Crohn's disease, and psoriasis (Elliott et al. 1994; Moreland et al. 2001). Currently inhibitors of intracellular signaling pathways such as the MAP kinase pathway are in trial. All of these approaches can reduce the APR including the APPs, leukocyte activation and migration, fever, etc. Not all these approaches will have exactly the same inhibitory effect but, with the reduction in inflammation, there may also come a risk that removal of some of these responses may have deleterious effects. At least at some level all these effects are likely to be beneficial to host function, particularly in terms of response to infection; to remove them may therefore increase risks of infection, although at least for TNFα blockade this appears to be a rare phenomenon.

The statins introduced to reduce cholesterol in atherosclerosis have been found to have an ability not only to reduce LDL cholesterol but also to reduce CRP and other APPs such as fibrinogen and SAA (Staels et al. 1998; Ridker et al. 2001). This control may be exerted through the peroxisome proliferator receptor α (PPARα), which not only alters lipid metabolism but has an anti-inflammatory role. It is possible that such effects are through transcription factors that induce CRP (Kleeman et al. 2003). In any event such treatment may be useful in other diseases that have an inflammatory component such as Alzheimer's disease, diabetes mellitus, or osteoporosis.

DISORDERS OF THE ACUTE PHASE RESPONSE

AA Amyloidosis

Serum amyloid A can, when present in high amounts for sufficient length of time (as, for example, in chronic diseases such as Crohn's disease or rheumatoid arthritis), give rise to deposits of a structurally altered AA amyloid protein that is resistant to degradation. This is thus one of the many forms of the amyloidosis diseases in which stable protein fibrils are deposited in vital organs. Although many of these amyloidoses can resolve they are capable, for example in AA amyloid, of destroying renal function and causing death if the balance remains in favor of deposition. These proteins are linked by the ability to switch conformation towards a β-pleated sheet-rich form that has resistance to degradation. In the case of SAA this is often accompanied by a cleavage of approximately 30 amino acids from the C-terminal end of the protein. Techniques to allow visualization of deposition of amyloid has demonstrated that AA amyloid deposits can regress (Hawkins et al. 1993) and more recently that depletion of the SAP component has the potential to be therapeutically useful (Pepys et al. 2002)

APP deficiences

As previously mentioned, deficiency in some anti-proteases leads to disease (see α_1-Antitrypsin or α_1-protease inhibitor). So far no patient with a deficiency of certain proteins such as CRP has been reported. However, the number of reports of deficiencies of particular APPs is increasing and, together with information from knock-out mice, the role of some of the proteins is in many cases not only confirming previous ideas but also providing some unexpected new observations.

Osteoporosis

Associated with increased proinflammatory cytokine levels, the balance of bone resorption and synthesis moves towards resorption. There is thus a tendency

towards osteoporosis. A number of proinflammatory cytokines and some newly discovered members of the TNF family regulate this process (Rodan and Martin 2000).

Systemic inflammation and shock

The ultimate effect of an uncontrolled APR is shock (see Shock/sepsis). Associated with such severe systemic inflammation, a further complication that may arise is acute respiratory distress syndrome. Sufficiently severe inflammation can also have the effect of apparently reducing immune responses (Lederer et al. 1999; Faunce et al. 2003). Lung function is compromised and so far one of the more promising ways of treating this is the use of neutrophil elastase inhibitors – a number of other potential treatments such as PAF antagonists having failed to have significant effect in clinical trials (Eaton and Martin 2002). There is considerable interest in some proteins that behave as APPs which seem to amplify the systemic inflammation. One such is high mobility group 1 protein (HMGB1) which can activate cells when released from necrotic cells. It is normally a nuclear protein which when released can behave as a cytokine (Andersson et al. 2002; Scaffidi et al. 2002). It is possible that this and other late mediators of inflammation might be more effective targets.

Chemokine actions on phagocytes	7		

Chemokine is a short form for chemotactic cytokine. The term was coined at a meeting in Baden near Vienna after the International Immunology Congress of Budapest (Lindley et al. 1993). Only few chemokines were known at that time and receptors for interleukin (IL)-8 had just been cloned and shown to belong to the family of G-protein-coupled receptors (GPCR) (Holmes et al. 1991; Murphy and Tiffany 1991). The importance of the new class of cytokines and their function as chemoattractants was already obvious, but no one in the field had anticipated the enormous and rapid development of research that led to a new understanding of leukocyte traffic (Baggiolini 1998; Loetscher et al. 2000; Sallusto et al. 2000; Gerard and Rollins 2001; Mackay 2001; Moser and Loetscher 2001; Murphy 2001; Thelen 2001). Chemokines are produced by leukocytes and tissue cells either constitutively or after induction, and act locally in a paracrine and possibly autocrine fashion on cells that express the appropriate GPCR. Chemotaxis is their main common effect.

A systematic nomenclature for chemokines was established recently (Zlotnik and Yoshie 2000). It is based on the principle adopted for chemokine receptors, which are defined as CXC, CC, XC, and CX_3C followed by R and a number. Chemokines are defined by the same structure-related acronyms followed by L (for ligand) and their gene number. Chemokine genes were originally designated as *SCY* (for small, secreted cytokines) and numbered chronologically. The systematic nomenclature is particularly useful for chemokines that were discovered in recent years, which have often been given more than one name. For IL-8, the monocyte chemoattractant proteins (MCP), RANTES, the macrophage infectivity potentiators (MIP), and other chemokines of the early days, however, the traditional names are still in current use (Tables 1 and 2 and Figure 1).

CHEMOKINES AND THEIR STRUCTURES

Chemokines are small soluble proteins with four conserved cysteines and molecular weights in the range 7–15 kDa (Baggiolini et al. 1994, 1997). They are synthesized with a leader sequence of 20–25 amino acids, which is cleaved off before release. Two main subfamilies, CXC and CC chemokines, are distinguished according to the position of the first two cysteines, which are adjacent (CC) or separated by one amino acid (CXC). The cysteines form two disulfide bonds linking Cys1 to Cys3 and Cys2 to Cys4, which keep the chemokines in a stable three-dimensional conformation that is required for receptor binding and activation. This structure has been resolved by nuclear magnetic resonance (NMR) in solution and X-ray crystallography. Chemokines have a prominent core made of anti-parallel β strands and the connecting loops, a short, conformationally disordered amino-terminal region (3–10 amino acids) and a carboxy-terminal α helix which usually consists of 20–30 amino acids, but can exceed 50. The NMR structure of stromal cell-derived factor 1 (SDF-1) (CXCL12) is presented as an example in Figure 2.

In concentrated solution and on crystallization several chemokines form dimers (Clore et al. 1990; Baldwin

et al. 1991). The mode of aggregation is strikingly different for CXC and CC chemokines, as illustrated in Figure 3 for IL-8 (CXCL8) and MIP-1α (CCL3). Studies of IL-8 (CXCL8), GROα (CXCL1), and NAP-2 (CXCL7) show that CXC chemokines associate along their first β strands via hydrogen bonds and amino acid side chain interactions (Baggiolini et al. 1997), whereas CC chemokines, e.g. MIP-1β (CCL4) (Lodi et al. 1994) and RANTES (CCL5) (Chung et al. 1995; Skelton et al. 1995) dimerize by interacting with their amino-terminal regions. It is believed that the distribution of hydrophobic areas on the surface, which is different for CXC

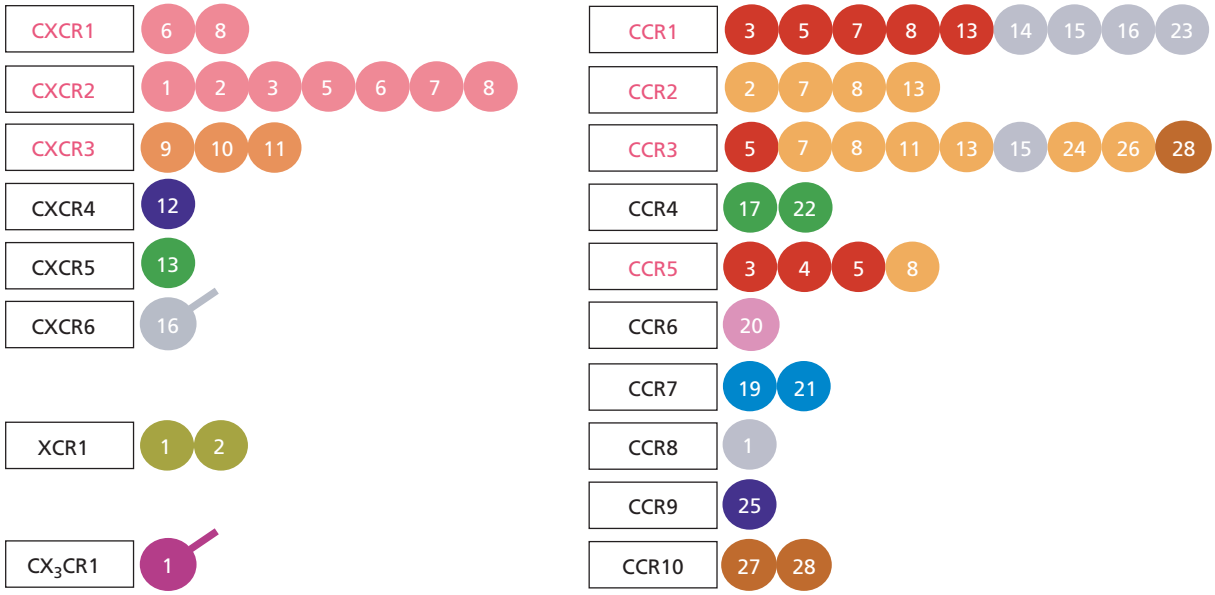

Figure 1 *Human chemokines and chemokine receptors: chemokines including the lymphotactins are presented as circles. Circles with a bar represent membrane-anchored chemokines. The numbers within the circles correspond to the chemokine numbers in the systematic nomenclature (see Tables 1 and 2). The colors of the circles indicate chemokines with structural similarities. Receptors for inflammatory chemokines are presented in red.*

and CC chemokines, determines the mode of dimer formation (Covell et al. 1994; Clore and Gronenborn 1995). The distribution of the inner hydrophobicity clusters, by contrast, is similar for chemokines of both subfamilies, explaining the common mode of folding of monomers.

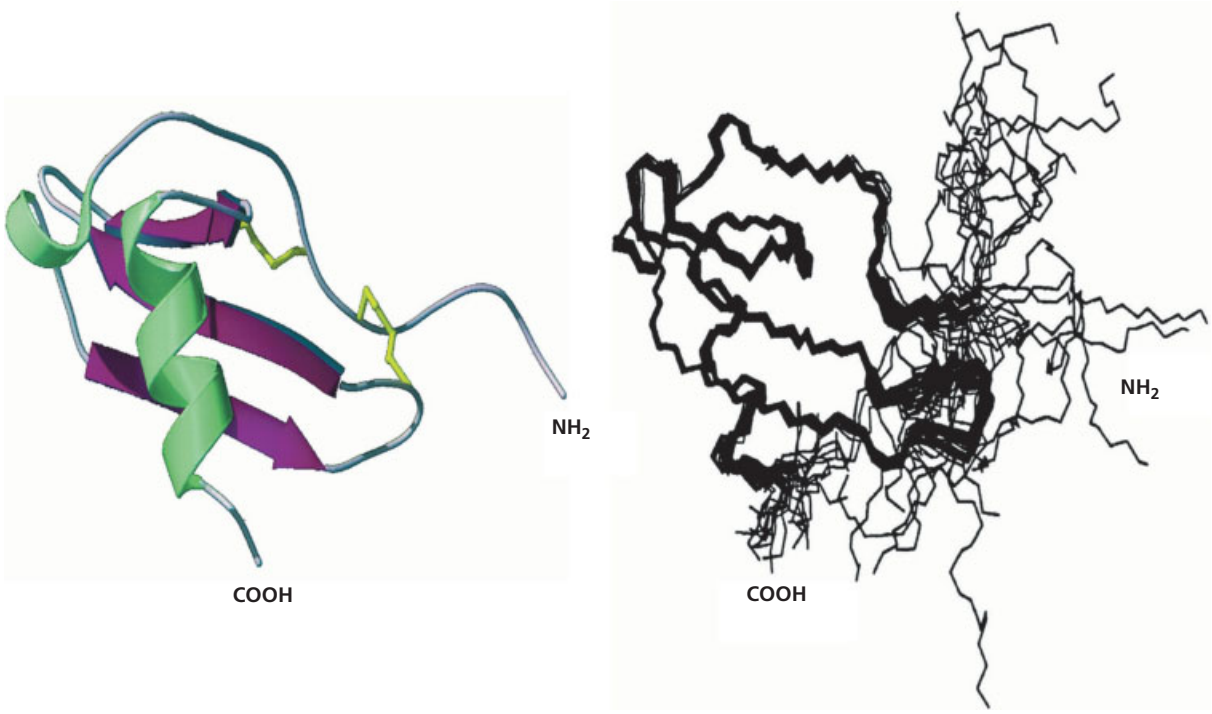

Figure 2 *Three-dimensional structure of the CXC chemokine SDF-1 (CXCL12) as obtained by NMR spectroscopy in solution. The model on the left shows the core consisting of anti-parallel β strands and the connecting loops, which is kept together by the disulfide bonds (in yellow), and presents an idealized view of the amino-terminal sequence and the carboxyl-terminal α helix. On the right, 30 single NMR views are projected on to each other. This presentation highlights the rigidity of the core and the structural disorder of the terminal regions. (Reproduced with permission from Crump et al. (1997).)*

Figure 3 *Dimer formation by CXC and CC chemokines as illustrated by IL-8 (CXCL8) and MIP-1α (CCL3). CXC chemokines associate along their first β strands (Gerber et al. 2000), whereas CC chemokines associate by interacting with their amino-terminal regions (Czaplewski et al. 1999). The mode of dimer formation is believed to reflect the different distribution of surface hydrophobicity areas in CXC and CC chemokines. The monomers of both subfamilies, by contrast, fold in the same manner because the distribution of the internal hydrophobicity clusters is similar.*

Aggregation was originally considered an important property and it was suggested that chemokines, like some cytokines, act as dimers (Baggiolini et al. 1997). It was eventually realized, however, that the biological activities of chemokines are observed at nanomolar concentrations, which are too low for stable aggregation to dimers (Burrows et al. 1994; Clark-Lewis et al. 1995). To demonstrate that IL-8 (CXCL8) can function as a monomer, an analogue of the 72 amino acid form was synthesized with *N*-methyl-leucine instead of leucine at position 25 to disturb hydrogen bonding and prevent dimerization. Although the analog remained monomeric, it was as active as wild-type IL-8 (CXCL8) (Rajarathnam et al. 1994). Similar results were obtained with monomeric forms of MIP-1α (CCL3) (Graham et al. 1994) and it was shown that some chemokines, MCP-3 (CCL7) for instance, do not dimerize (Kim et al. 1996). As monomeric chemokines have full biological activity and aggregation occurs at concentrations that are much higher than those required for a chemotactic response, there is little doubt today that the biologically relevant conformation of chemokines is the monomer (Clark-Lewis et al. 1995).

Two variants of the chemokine structure paradigm have been described: lymphotactin (XCL1, XCL2) with two instead of four conserved cysteines (Kennedy et al. 1995) and fractalkine or neurotactin (CX_3CL1), a membrane-bound mucin bearing an amino-terminal chemokine-like domain with three amino acids between the first two cysteines (CX_3C motif) (Bazan et al. 1997; Pan et al. 1997).

RECEPTOR BINDING AND ACTIVATION

The receptor for chemotactic *N*-formyl-methionyl peptides was cloned more than a decade ago (Boulay et al. 1990) and found to have a heptahelical structure and to couple to heterotrimeric GTP-binding proteins. The cloning of the first chemokine receptors, two heptahelical proteins with high affinity for IL-8 (CXCL8), followed soon thereafter (Holmes et al. 1991; Murphy and Tiffany 1991). Meanwhile six human receptors for CXC chemokines and ten for CC chemokines, in addition to the receptors for lymphotactin and fractalkine, have been characterized (Murphy et al. 2000; Murphy 2002). The study of receptor selectivity and expression in different types of leukocytes has provided considerable insight into the mechanism for the specific recruitment of different types of leukocytes and the regulation of leukocyte traffic in health and disease. Blood phagocytes, for instance, express different types and combinations of chemokine receptors. CXCR1 and CXCR2 are found exclusively in neutrophils, the front-line cells for antibacterial defense. Eosinophil and basophil granulocytes as well as monocytes share CCR1, but can be recruited selectively by chemokines acting on CCR3, for eosinophils and basophils, or CCR5 for monocytes (Figure 4).

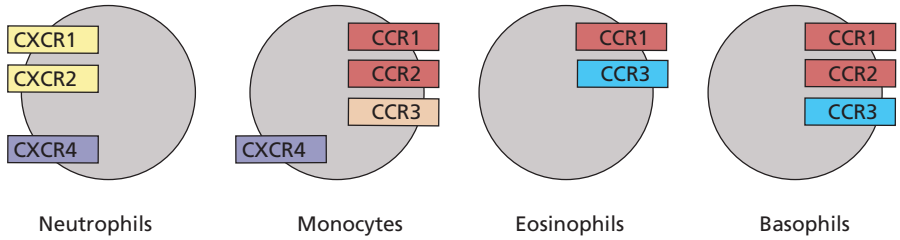

Figure 4 *Chemokine receptor expression in human phagocytic leukocytes.*

The search for sequence domains that are involved in receptor recognition and activation began after the characterization of the receptors for IL-8 (CXCL8) and related chemokines. These studies revealed the importance of the amino-terminal region and showed that a sequence of three residues, Glu-Leu-Arg, the so-called ELR motif, immediately preceding the first cysteine, is essential for IL-8 (CXCL8) activity (Clark-Lewis et al. 1991, 1993; Hébert et al. 1991). The ELR motif is conserved in all IL-8 (CXCL8)-related chemokines, the growth-related oncogene (GRO) proteins (CXCL1–3), ENA-78 (CXCL5), granulocyte chemoattractant protein 2 (GCP-2) (CXCL6), and neutrophil-activating protein 2 (NAP-2) (CXCL7), and is necessary for activation of CXCR1 and CXCR2 (Baggiolini et al. 1994, 1997). Neither receptor, however, responds to linear or cyclic oligopeptides enclosing the Glu-Leu-Arg-Cys-X-Cys sequence or to unrelated chemokines such as MCP-1 (CCL2) and interferon-inducible protein 10 (IP10) (CXCL10) that were modified by insertion of an ELR-containing amino-terminal sequence (Clark-Lewis et al. 1993). These observations indicated that other recognition sites are required. Using mutagenesis or chemical synthesis of analogues of the 72-residue form of IL-8 (CXCL8), such sites were identified in the loop region following the second cysteine (residues 10–17) and in the sequence immediately preceding the third cysteine (Clark-Lewis et al. 1994, 1995). Discrete differences between IL-8 (CXCL8) and its analogs, e.g. NAP-2 (CXCL7) and GROα (CXCL1) (Kim et al. 1994), determine the binding selectivity for CXCR1 and CXCR2.

Similar studies performed with several other CC and CXC chemokines confirmed the importance of the amino-terminal region for receptor activation (Loetscher and Clark-Lewis 2001; Fernandez and Lolis 2002). In most cases, however, receptor-triggering motifs could not be unequivocally identified. MCP-1, for instance, requires the entire sequence of 10 amino acids preceding the first cysteine for full activity on CCR2. Potency drops considerably after truncation or elongation of the amino-terminal sequence, but the amino-terminal residue can be replaced by several amino acids without affecting activity (Clark-Lewis et al. 1995). MCP-1, MCP-2, MCP-3, and MCP-4 (CCL2, CCL8, CCL7, and CCL13), which are all potent agonists for CCR2, share the amino-terminal Gln-Pro motif and have other similarities within the first 10 residues. Despite these analogies, the structure–activity relationships are far from clear. In contrast to MCP-1 (CCL2), all three analogs act on additional receptors, CCR3 in particular. On the other hand, MCP-1 (CCL2) itself becomes a high-affinity ligand for CCR3 after deletion of glutamine at the amino terminus, which causes a 50-fold drop in affinity for CCR2 (Weber et al. 1996).

Of particular interest are the structure–activity relations studies on SDF-1 (CXCL12) (Crump et al. 1997; P. Loetscher et al. 1998a), the exclusive ligand for CXCR4, a receptor that is widely expressed in leukocytes and tissue cells and functions as a co-receptor for HIV (Murphy et al. 2000). The first amino-terminal residues of SDF-1 (CXCL12), Lys1-Pro2, are essential for receptor triggering: deletion of Lys1 dramatically decreases activity and the deletion of both amino acids fully inactivates the chemokine. As for IL-8 (CXCL8), some residues in the loop region of SDF-1 (CXCL12) immediately after the second cysteine (residues 12–17, RFFESH motif) are required for receptor binding (Crump et al. 1997). The importance of the amino-terminal domain of SDF-1 is underscored by an astonishing observation: GROα (CXCL1), a selective ligand of CXCR2, and IP10 (CXCL10), a selective ligand of CXCR3, can be converted into agonists for CXCR4 by substituting their amino-terminal domain with the first 17 residues of SDF-1 (CXCL12). Interestingly, CXCR4 triggering was also obtained with an oligopeptide consisting only of the first 17 residues of SDF-1 (P. Loetscher et al. 1998a), which folds in a similar way to the wild-type chemokine (Elisseeva et al. 2000).

All studies of structure–activity relationships indicate the importance of the amino-terminal domain of CXC and CC chemokines for receptor recognition and activation (Clark-Lewis et al. 1995; Loetscher and Clark-Lewis 2001). Two separate or partly overlapping sites of interaction with the receptors can be distinguished, one in the amino-terminal sequence preceding the first cysteine and the other within the exposed, conformationally rigid loop after the second cysteine (N loop). Both sites are small (consisting of few amino acids) and are kept in close proximity by the disulfide bonds (see Figure 2).
Clark-Lewis and colleagues (Crump et al. 1997) have proposed that the receptor recognizes first the binding site within the loop region, which functions as a *docking*

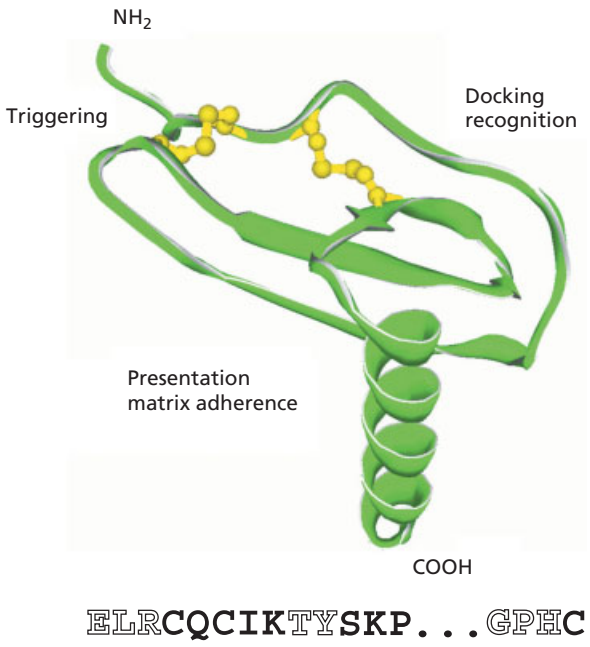

Figure 5 *Chemokine-binding domains: chemokines interact with their receptors by means of two discrete, contiguous, or slightly overlapping domains. The receptor is recognized via a binding site within the loop region, which appears to function as a* docking domain*. This interaction restricts the mobility of the chemokine and presumably facilitates the proper orientation of the amino-terminal* triggering domain *which activates the receptor. Chemokines tend to bind to glycosaminoglycans on the surface of cells or in the extracellular matrix via basic residues of the core and the carboxy-terminal region. Bound chemokines retain their full chemotactic activity.*

domain. This interaction restricts the mobility of the chemokine and presumably facilitates the proper orientation of the amino-terminal *triggering domain* that activates the receptor (Figure 5).

INTRACELLULAR SIGNALING

Chemokine signaling was first studied in human neutrophils stimulated with IL-8 (CXCL8). It was found that all functional responses were blocked when the cells were pre-treated with *Bordetella pertussis* toxin, indicating that the receptor couples to GTP-binding proteins of the Gi type (Thelen et al. 1988), which eventually turned out to be the rule for all chemokine receptors (Murphy et al. 2000). When a chemokine binds to its receptor, heterotrimeric Gi proteins are activated: GDP, which is bound to the inactive trimeric complex, is exchanged for GTP, and the complex dissociates into its α subunit bound to GTP and the $\beta\gamma$ subunit. The release of the $\beta\gamma$ subunit is essential for the stimulation of chemotaxis (Neptune and Bourne 1997), which involves the activation of the rho GTPases Rac and CDC42, the Wiscott–Aldrich syndrome protein (WASP), and the Arp2/3 complex, and leads to actin polymerization (Cory and Ridley 2002). In addition the $\beta\gamma$ subunit activates two major signal transduction enzymes: a phospholipase C ($PLC\beta_2$ and-β_3) which is specific for phosphatidylinositol, and a phosphatidylinositol-3-hydroxyl kinase ($PI3K\gamma$). The phospholipase cleaves phosphatidylinositol 4,5-bisphosphate, yielding two second messengers: inositol 1,4,5-trisphosphate (IP_3) and diacylglygerol (DAG). IP_3 induces the release of Ca^{2+} from intracellular stores, leading to a characteristic, transient rise of the free calcium concentration, and DAG activates several isoforms of protein kinase C (PKC). The IP_3 kinase generates phosphatidylinositol 3,4,5-trisphosphate and initiates the activation of another kinase, PKB. There is evidence that the $\beta\gamma$ subunit of the Gi protein may activate other signaling kinases, such as the MAP kinase, but the mechanism and the role of this step are still unclear (Thelen 2001). The signaling that is initiated with the exchange of GTP for GDP and the consequent dissociation of the α and $\beta\gamma$ subunits is terminated by the hydrolysis of GTP to GDP and the re-association of the $\beta\gamma$ subunit with the GDP-bound α subunit. Newer findings suggest that the α subunit is more than a binding moiety that regulates the activity of the $\beta\gamma$ subunit, and signals on its own by activating tyrosine kinases (Thelen 2001).

The signal transduction events induced by IL-8 (CXCL8) appear to correspond to those observed after stimulation with the classic chemotactic agonists such as fMet-Leu-Phe (formyl-methionine-leucine-phenylalanine) and C5a (Baggiolini and Kernen 1992). Using Jurkat cells stably transfected with CXCR1 or CXCR2 copy DNA (cDNA), it was shown that both receptors respond equally well to IL-8 (CXCL8), as judged by the activation of p42/p44 MAP kinase (Jones et al. 1995), Ca^{2+} mobilization and chemotaxis (Loetscher et al. 1994a), and that the two IL-8 receptors function independently of each other. By blocking one or the other receptor in neutrophils using monoclonal antibodies it was found that phospholipase D activation and the respiratory burst are mediated by CXCR1 only (Jones et al. 1996). In agreement with these observations, it was reported that phospholipase D is activated by stimulation with IL-8 (CXCL8), but not with GROα (CXCL1) or NAP-2 (CXCL7) (L'Heureux et al. 1995).

In contrast to other chemokines, which induce short-lived responses, SDF-1 (CXCL12) was found to mediate the prolonged activation of protein kinase B and the MAP kinases ERK1/2 via CXCR4 (Tilton et al. 1997). The sustained effect on intracellular signaling reflects the continuous interaction of CXCR4 with its ligand. Such activity may be required for the retention pre-B cells at their sites of maturation within the bone marrow (Ma et al. 1999). Prolonged activation of protein kinase B was shown to protect cells from apoptosis (Marte and Downward 1997). Prolongation of cell survival is an as yet unexplored effect mediated by CXCR4, which is widely expressed in leukocytes and nonhemopoietic cells.

It was recently reported that after stimulation chemokine receptors form homo- or heterodimers (Mellado et al. 2001). Up to now, this mechanism has not received general acceptance and its role in the initiation of chemokine responses has been questioned (Thelen and Baggiolini 2001). The existence of GPCR dimers is documented by studies showing that aggregation may pre-exist or occurs slowly after stimulation (Bouvier 2001; Pierce et al. 2002), suggesting that dimerization is too slow as an initiating event.

ASSESSING CHEMOKINE ACTIVITIES

The most common test for chemokine activity is chemotaxis in a two-well chamber where leukocytes, which are placed in the upper well, migrate through a porous polycarbonate membrane in response to chemokines supplied in the lower well. The cells sense chemokine molecules that diffuse across the membrane and move toward higher concentrations of the attractant. The pores are always smaller than the migrating cells, and their diameter is chosen depending on the properties of the cells, in particular their size and mobility. Migration is assessed by counting the cells that have crossed the membrane and stick to its lower surface or fall into the fluid of the lower well. Coating of the lower membrane surface with collagen is used to increase sticking for the purpose of recovering migrated cells on the lower surface of the filter. The crossing of a polycarbonate membrane is a simple model of diapedesis, the migration of leukocytes through the endothelial layer and the basement membrane of microvessels, which is the first step of the intervention of host-defense cells in infection and inflammation.

The dependence of the chemotaxis response in vitro on chemokine concentration is usually bimodal: the number of migrating cells increases up to an optimum concentration and then falls, because over-stimulation increasingly leads to adherence (Baggiolini et al. 1994). Migration may also be assessed in vivo by monitoring the infiltration of leukocytes into a tissue area or a body cavity where a chemokine is injected. The infiltration can be quantified by image analysis of histology or cytochemistry specimens (Uguccioni et al. 1999), by counting the leukocytes collected in an exudate or by measuring the radioactivity of tissue sites in animals supplied with radioactively labeled leukocytes (Colditz et al. 1989). Furthermore, vital microscopy may be used in microcirculation experiments to observe chemokine-induced rolling and adhesion of leukocytes on the endothelial surface (Stein et al. 2000; Warnock et al. 2000).

The migration across the wall of microvessels and within the tissues along a chemokine concentration gradient is a complex function resulting from the combination of discrete responses. Some of these responses can be measured in real time as in vitro correlates of chemotaxis. Early studies on neutrophils stimulated with IL-8 (CXCL8) have shown that chemokines induce rapid, active changes in cellular shape as a result of the polymerization and depolymerization of actin (Thelen et al. 1988). Other characteristic effects are the upregulation and activation of integrins through which the leukocytes adhere to endothelial cells before emigration (Springer 1994), the release of granule contents, e.g. proteases from neutrophils, monocytes, $CD8^+$ T lymphocytes, and natural killer (NK) cells, histamine from basophils and cytotoxic proteins from eosinophils, the production of bioactive lipids, and the formation of oxygen radicals during the respiratory burst (Baggiolini et al. 1994, 1997). The release responses are observed at higher chemokine concentrations and are enhanced when the leukocytes are exposed to bacterial toxins or inflammatory cytokines. It must be assumed that release occurs once the leukocytes have reached their target, e.g. a site of infection and inflammation, where they stop migrating and perform antimicrobial and other functions in host defense (Baggiolini et al. 1994, 1997).

As already mentioned the second messenger inositol trisphosphate releases Ca^{2+} from intracellular stores, leading to a transient rise of its free concentration in the cytosol, which is one of the earliest cellular responses to chemoattractants (von Tscharner et al. 1986a, 1986b). With appropriate instruments one can measure the rate of the increase of Ca^{2+}-related fluorescence, which reflects the intensity of chemokine effects in real time and is the most reliable method to assess concentration–response relationships. We have used this assay extensively for the analysis of chemokine receptor selectivity and desensitization (Uguccioni et al. 1995, 1996; P. Loetscher et al. 1994b, 1996; Forssmann et al. 1997; Bardi et al. 2001).

CHEMOKINE ACTIONS ON PHAGOCYTES

As shown in Figure 4, phagocytes rely on a small repertoire of chemokine receptors, CXCR1 and CXCR2 for neutrophils, CCR1, CCR2, CCR3, and CCR5 for eosinophils, basophils, and monocytes. They are expressed constitutively and are always detectable and functional on the phagocytes that circulate in the blood. The receptors are ready for rapid interventions in response to chemokines induced in endothelial cells and in the tissues under pathological conditions by inflammatory stimuli such as bacterial toxins, inflammatory cytokines, such as IL-1, tumor necrosis factor (TNF), and interferons, hemopoietic growth factors, bioactive lipids, oxygen radicals, etc. (Baggiolini et al. 1994). Even though receptor numbers may change when the cells are activated (Bonecchi et al. 1999, 2000), their repertoire remains characteristic for each type of phagocyte. The system that drives phagocyte recruitment is redundant: most receptors recognize more than one chemokine and several chemokines act on multiple receptors (see

Figure 1). CXCR4, the selective receptor for SDF-1 (CXCL12), which is found in neutrophils and monocytes, makes an exception, because its role for these cells is unknown. In addition, phagocytes express several other receptors for nonchemokine ligands, like the complement product C5a, *N*-formyl-methionyl peptides, and several bioactive lipids, which may all contribute to phagocyte recruitment in inflammation (Boulay et al. 1997).

The ligands of CXCR1, CXCR2, CCR1, CCR2, CCR3, and CCR5 are collectively referred to as *inflammatory chemokines* because they are released in pathological conditions and disturbances of tissue homeostasis leading to inflammation. As a rule these chemokines are not detectable in healthy tissues. Numerous publications document the expression of CXC and CC chemokines at sites of inflammation, infection, and immune reactions. The main sources are different types of tissue cells, tissue macrophages, mast cells, but also the phagocytes that enter the inflamed tissues, which amplify in this way inflammatory and host-defense reactions by contributing to further cell recruitment (Baggiolini et al. 1994, 1997).

Inflammatory chemokines act as well on lymphocytes and other effector cells of acquired immunity. $CD4^+$ and $CD8^+$ T cells (Loetscher et al. 2000; Sallusto et al. 2000), NK cells (Maghazachi and Al-Aoukaty 1998), and immature dendritic cells (Sozzani et al. 1999) can express CCR1, CCR2, CCR3, and CCR5, and are thus readily attracted into inflamed tissues. In addition T and NK cells express CXCR3, which is upregulated in lymphocytes together with the other receptors for inflammatory CC chemokines indicated, and respond to a monokine induced by interferon γ (Mig), IP10, and interferon-inducible T-cell α-chemoattractant (I-TAC) (CXCL9, 10, and 11, respectively), which are induced in inflamed tissues by interferon γ (IFN-γ). CXCR3 is the only receptor for inflammatory chemokines that is not found in phagocytes.

CHEMOKINE ACTIONS ON LYMPHOCYTES

Memory and effector functions

In contrast to phagocytes, which leave the bloodstream to enter tissues where they perform host-defense functions and eventually die, but never return to the blood, lymphocytes circulate continuously through lymphoid and nonlymphoid tissues in search of antigens to provide specific protection against pathogens (Mackay 1993; Butcher and Picker 1996). When naïve T cells, in secondary lymphoid tissues, encounter an antigen they are activated, differentiate into effector or memory cells, and proliferate. Unlike their naïve precursors, effector and memory lymphocytes usually migrate into nonlymphoid tissues, which are the prime sites of entry for microorganisms and other foreign antigens. They have, however, the ability to home again into secondary lymphoid tissues for renewed episodes of activation. Recent research has shown that the various re-circulation itineraries are regulated by the expression of chemokine receptors on the lymphocytes and of the appropriate chemokines in the homing areas as well as adhesion molecules (Sallusto et al. 2000; Von Andrian and Mackay 2000; Moser and Loetscher 2001).

Early studies had suggested that T lymphocytes isolated from the blood respond poorly to chemokines. When T cells, however, are kept in culture in the presence of IL-2 the expression of several receptors for inflammatory chemokines, namely CCR1, CCR2, CCR5, and CXCR3, is markedly enhanced and migration in responses to the respective ligands, such as RANTES (CCL5), MCP-1 (CCL2), MIP-1β (CCL4), and IP10 (CXCL10), increases progressively (M. Loetscher et al. 1998; P. Loetscher et al. 1996). IL-4, IL-10, and IL-12 have similar effects but are less potent, whereas other cytokines known to act on T lymphocytes (IL-13, IFN-γ, IL-1β, and TNFα) are inactive. The effect is reversible: Receptor expression and responsiveness are rapidly lost when IL-2 is withdrawn, and are fully restored when it is added again (P. Loetscher et al. 1996). Rapid down-regulation of receptors for inflammatory chemokines is also observed when IL-2 is replaced by anti-CD3 alone or in combination with anti-CD28, mimicking activation via the T-cell receptor. These observations created much interest and several laboratories began systematically to study chemokine receptor expression in relation to T-lymphocyte differentiation.

T-lymphocyte-dependent immune responses rely on helper cells of T-helper (Th)1 or Th2 phenotype with different functional properties (Mosmann and Coffman 1989; Abbas et al. 1996), which develop from naïve precursors after antigen recognition and priming. Th1 cells secrete IFN-γ and lymphotoxin and enhance cell-mediated immunity to intracellular pathogens, whereas Th2 cells secrete IL-4 and IL-5, and regulate allergic responses and humoral immunity against parasites. A lymphocyte infiltrate may be of Th1 or Th2 type depending on the pathological conditions, and it was natural to assume that the selective recruitment of cells of either phenotype is driven by the chemokine receptors that they bear and the chemokines expressed in the diseased tissues.

CCR3, a receptor that was originally identified in eosinophils and basophils and that binds several chemokines including the eotaxins (see Figure 1), is expressed on a subset of blood T lymphocytes which produce IL-4 and IL-5 and thus qualify as Th2 cells (Sallusto et al. 1997). CCR3 is also expressed at high levels in Th2-type cells, which are obtained by culturing umbilical cord blood lymphocytes activated with phytohemagglutinin in the presence of IL-4 and neutralizing anti-IL-12 antibodies (Sallusto et al. 1997, 1998), and in cloned, allergen-

specific T cells with a Th2 phenotype (Gerber et al. 1997). CCR3-positive Th2 cells are recruited together with eosinophils to sites of allergic inflammation, and are likely to support eosinophil survival by secreting IL-4 and IL-5 (Gerber et al. 1997). Without questioning the fact that CCR3 is found in Th2 and not in Th1 cells, it is important to note that the level of CCR3 expression in Th2 lymphocytes was shown in several studies to be moderate and variable, suggesting that CCR3-bearing cells constitute a Th2 subpopulation (Loetscher et al. 2000).

CCR4 and CCR8 are also considered as characteristic for Th2 lymphocytes (D'Ambrosio et al. 1998; Zingoni et al. 1998; Imai et al. 1999). Both receptors are transiently upregulated in Th2 cells after stimulation in culture with anti-CD3 and anti-CD28. In contrast to CCR8, which is present exclusively in activated Th2 cells, CCR4 appears to be expressed constitutively and is also found in Th1 cells on activation with anti-CD3 and anti-CD28 (D'Ambrosio et al. 1998).

CCR5 is expressed preferentially in Th1 cells (Annunziato et al. 1998; Bonecchi et al. 1998; P. Loetscher et al. 1998b; Siveke and Hamann 1998). It is detected in Th1 and Th2 cells obtained from umbilical cord blood by treatments inducing polarization, but is not expressed in cloned Th2 cells (P. Loetscher et al. 1998b; Sallusto et al. 1998). Th1 lymphocytes also express high levels of CXCR3, the receptor for Mig, IP10, and I-TAC (CXCL9, 10, and 11, respectively) (Cole et al. 1998; P. Loetscher et al. 1998b; Qin et al. 1998). We and others have found that CXCR3 is present in both types of helper cells after proliferation induced with IL-2 (Annunziato et al. 1998; P. Loetscher et al. 1998b), whereas preferential expression in Th1 cells has been observed under other conditions (Bonecchi et al. 1998; Sallusto et al. 1998). Cytochemical analysis shows that the abundant Th1 lymphocyte infiltrate in the synovial pannus of rheumatoid arthritis joints is strongly positive for CCR5 and CXCR3, whereas CCR3 is virtually absent (P. Loetscher et al. 1998b; Qin et al. 1998).

A similar chemokine receptor pattern is observed in cytotoxic T cells (Tc): CCR5 is present in Tc1 whereas enhanced levels of transcripts for CCR3, CCR4, and CCR8 are characteristic for Tc2 cells (D'Ambrosio et al. 1998). It was recently reported that CXCR6 is preferentially expressed in blood Th1 and Tc1 cells and that CXCR6-positive $CD4^+$ and $CD8^+$ T cells are enriched in the synovial fluid of rheumatoid arthritis joints (Kim et al. 2001b). Such observations have been confirmed and extended in several studies emphasizing the role of chemokines and their receptors in directing lymphocyte traffic under physiological and pathological conditions (Sallusto et al. 2000; Von Andrian and Mackay 2000; Moser and Loetscher 2001).

A particularly important role in lymphocyte traffic and for the identification of cells with distinct functional properties is ascribed to CCR7. Sallusto et al. (1999) have defined two subsets of human memory T lymphocytes, one comprising cells without immediate effector properties, termed central memory T cells (T_{CM}), which are CCR7 positive, and the other comprising IL-4 and IFN-γ producing, perforin-positive cells, termed effector memory T cells (T_{EM}), which lack CCR7, but bear inflammatory chemokine receptors including CXCR3 and CCR5. The receptor profile underscores the different role played by these cells in a secondary immune response. T_{EM} cells can be recruited rapidly into inflamed tissues for immediate defense, whereas T_{CM} cells, which represent a clonally expanded memory cell pool, enter lymph nodes after a secondary antigen challenge, where they may stimulate dendritic cells to produce IL-12, provide help to antigen-specific B cells, and generate a new wave of effector T cells (Sallusto et al. 1999; Masopust et al. 2001; Reinhardt et al. 2001).

The concept of central and effector memory lymphocytes has recently been questioned in a number of reports. According to the model, CCR7 expression should be lost in memory $CD4^+$ T lymphocytes homing into the skin and the gut, and in fully differentiated, cytokine-producing Th1 and Th2 cells. However, in human blood, most memory $CD4^+$ lymphocytes with skin- or gut-homing markers (CLA^+ and $\alpha4\beta7^+$, respectively) were reported to bear CCR7 (Campbell et al. 2001), and the same was observed for a substantial fraction of IFN-γ- or IL-4-producing effector $CD4^+$ T lymphocytes (Kim et al. 2001c; Debes et al. 2002). It was also reported that CCR7-positive $CD4^+$ and $CD8^+$ memory T lymphocytes, arising in mice after viral infection, produce IFN-γ and exhibit lytic activity, respectively (Unsoeld et al. 2002). As they bear CCR7, such cells retain the capacity to re-circulate through secondary lymphoid tissues. The apparent discrepancy between the original and the subsequent reports should be clarified by further studies.

Much attention has recently been given to CXCR5, the selective receptor for BCA-1 (BLC in the mouse, CXCL13), to identify lymphocytes with distinct homing and effector properties (Mackay 2000; Kim et al. 2001a; Moser et al. 2002). CXCR5 is expressed in mature, circulating B lymphocytes and a subset of memory T cells (Förster et al. 1994; Breitfeld et al. 2000; Schaerli et al. 2000; Kim et al. 2001d). It is present in about 20 percent of the blood $CD4^+CD45RO^+$ T lymphocytes, which also express CCR7 but do not produce effector cytokines, suggesting that they qualify as T_{CM} cells. $CXCR5^+$ and $CCR7^+$ blood lymphocytes are considered as the precursors of the follicular B-helper T (T_{FH}) cells found in the B-cell areas of secondary lymphoid tissues. In the tonsils, most $CD4^+$ memory T cells express CXCR5. They have a B-helper function, which is particularly evident in $CD57^+$ T cells from germinal centers, and markedly enhance antibody production when co-cultured with B cells (Breitfeld et al. 2000; Schaerli et al. 2000; Kim et al. 2001d). Naïve blood T lymphocytes

rapidly acquire CXCR5 on activation in vitro with antigen-presenting dendritic cells and irreversibly lose expression of this receptor after terminal differentiation to effector cells (Schaerli et al. 2001). Together, these observations show that CXCR5-bearing T lymphocytes constitute a unique subset that is distinct from Th1 and Th2 cells.

Homing into lymphoid tissues

The role of chemokines in lymphocyte homing has already been addressed in the context of immune defense, but it is important to highlight their critical involvement in the formation and the renewal of secondary lymphoid tissues, e.g. lymph nodes and Peyer's patches, through the recruitment of naïve cells, a process that depends on two chemokine receptors, CCR7 and CXCR5, and their ligands (Sallusto et al. 2000; Von Andrian and Mackay 2000; Moser and Loetscher 2001).

The recognition that chemokines direct the homing of lymphocytes into secondary lymphoid tissues goes back to a remarkable experiment by Lipp and colleagues (Förster et al. 1996) who found that deletion of the gene of the then putative chemokine receptor termed 'BLR1' or 'MDR15', which was cloned from Burkitt's lymphoma (Förster et al. 1994) and human monocytes (Barella et al. 1995), resulted in impaired formation of Peyer's patches and inguinal lymph nodes. B cells lacking BLR1 were unable to enter their area of destination. The ligand for BLR1 was soon found to be a chemokine, termed 'BCA-1' or 'BLC' (CXCL13), and the receptor was renamed CXCR5 (Gunn et al. 1998; Legler et al. 1998). BCA-1/BLC (CXCL13) is selectively expressed in the B-cell follicles and deletion of the *BLC* (CXCL13) gene in mice yields the same phenotype as the deletion of the CXCR5 gene (Ansel et al. 2000).

Subsequent studies elucidated the role of CCR7, which binds two chemokines – secondary lymphoid tissue chemokine (SLC) (CCL21) and Epstein–Barr virus-induced receptor ligand chemokine (ELC) (CCL19) – and is expressed in all naïve and part of memory T lymphocytes as well as on B lymphocytes (Loetscher et al. 2000; Sallusto et al. 2000). In response to SLC (CCL21), which is expressed in high-endothelial venules, T lymphocytes enter secondary lymphoid tissues and are then attracted within the parafollicular area by SLC (CCL21) and ELC (CCL19), which are co-expressed there. The receptor and the ligands are essential for the homing and distribution of T lymphocytes as illustrated by deletion of the corresponding genes. Mice lacking CCR7 present morphological abnormalities, reflecting a disturbed homing of T cells into lymph nodes, and are unable to mount adequate antibody and delayed-type hypersensitivity responses (Förster et al. 1999). Similar disturbances are observed in mice with the *plt* (paucity of lymph node T cells) syndrome resulting from defective SLC (CCL21) and ELC (CCL19) expression (Gunn et al. 1999; Stein et al. 2000; Warnock et al. 2000).

Despite the disturbance of T lymphocytes homing, *plt* mice have a nearly normal B-lymphocyte recruitment into secondary lymphoid organs (Nakano et al. 1997). CCR7-deficient B lymphocytes transferred into normal mice, however, accumulate less efficiently in lymph nodes and Peyer's patches (Förster et al. 1999). Using transferred chemokine receptor-deficient and chemokine-desensitized B lymphocytes, it has recently been shown, by intravital microscopy, that B-cell homing into lymph nodes depends on two receptors – CCR7 and CXCR4 – and that, in addition, CXCR5 is important for B-cell homing into Peyer's patches (Okada et al. 2002). As shown by experiments in mice, the positioning of B cells in lymphoid tissues depends on responsiveness to BLC (CXCL13), on the one hand, and ELC and SLC (CCL19, CCL21), on the other, which are expressed in the B- and the T-cell areas, respectively (Reif et al. 2002). Naïve B cells, which bear CXCR5, migrate into the B-cell area in response to BLC (CXCL13). After antigen encounter and activation, however, B cells upregulate CCR7 and are attracted by SLC (CCL21) and ELC (CCL19) to the boundary between the B-and T-cell area (Reif et al. 2002).

In contrast to B2 cells (the conventional B cells), B1 cells home preferentially to the peritoneal and pleural cavities where macrophages and omentum cells constitutively produce BLC. B1 cells are a significant source of serum antibodies and make a major contribution to natural antibody production (low-affinity immunoglobulin M or IgM). In mice lacking BLC (CXCL13), the immigration of B1 cells into the peritoneal and pleural cavities is impaired and the production of natural and antigen-specific antibodies is markedly decreased (Ansel et al. 2002). Additional evidence for the important role of BLC (CXCL13) in homing of B1 cells is provided by the observation that B1 cells accumulate in the kidney and the thymus of aging BWF1 mice as a result of the abnormal expression of BLC (CXCL13) by myeloid dendritic cells (Ishikawa et al. 2001).

Another aspect of homing is the relocation of cells within a lymphoid tissue during maturation and differentiation as observed for thymocytes, which change receptor expression as they move from cortical to intermediate and then medullar sites (Campbell et al. 1999b; Annunziato et al. 2001; Ansel and Cyster 2001). Chemokines that are selectively produced in the different thymic areas are believed to retain the thymocytes as long as they express the proper chemokine receptor. A similar mechanism may operate in lympho- and myelopoiesis. Before being recognized as a chemokine, SDF-1 (CXCL12) was described as a factor with co-stimulatory effects on B-cell precursors (Tashiro et al. 1993; Nagasawa et al. 1994). We found that this chemokine attracts pre- and pro-B cells in contrast to more mature forms,

and suggested that it could stimulate lymphopoiesis by attracting maturing cells in the vicinity of growth factor-producing stromal cells (D'Apuzzo et al. 1997; Baggiolini 1998). In agreement with this hypothesis, deletion of CXCR4 in mice resulted in enhanced escape of B-cell precursors into the circulation (Ma et al. 1999).

Homing into nonlymphoid tissues

Chemokines and their receptors are also involved in the regulation of T-cell traffic through nonlymphoid tissues. It has been suggested that memory T cells show a selective tropism for specific peripheral tissues and re-circulate preferentially through the tissues where they have acquired their immunological memory (Mackay 1993). Good examples are the skin-homing and gut-homing memory T cells, which are characterized by the expression of adhesion molecules, the cutaneous lymphocyte-associated antigen (CLA), and the integrin $\alpha_4\beta_7$, which co-determine their homing selectivity. CLA binds to E-selectin expressed on endothelial cells in the skin, whereas $\alpha_4\beta_7$ binds to mucosal addressin-cell adhesion molecule-1 (MadCAM-1) expressed in the endothelia of mucosal tissues. The homing preference of the cells is also reflected by the chemokine receptors that they express, CCR4, CCR9, and CCR10 in particular, and by the production of the corresponding chemokines in the tissues.

CCR4 is present on all CLA-positive and other memory T cells, but absent from $\alpha_4\beta_7$ memory T cells (Campbell et al. 1999a; Andrew et al. 2001). TARC (CCL17), one of CCR4's two selective ligands, is expressed by normal and inflamed endothelium of the skin, but not of the intestine (Campbell et al. 1999a). About a third of CLA^+ T cells also bear CCR10 and thus migrate in response to its two ligands, CTACK (CCL27) and MEC (CCL28) (Morales et al. 1999; Homey et al. 2000, 2002; Pan et al. 2000; Wang et al. 2000). CTACK (CCL27) is a skin-associated chemokine (Morales et al. 1999) that is produced in the basal layers of the epidermis and is upregulated in inflammatory skin diseases (Homey et al. 2002). In two different mouse models of allergen-challenged skin, anti-cutaneous T-cell attracting chemokine (CTACK) antibodies markedly inhibited the recruitment of lymphocytes and tissue swelling (Homey et al. 2002). A role for CCR4 and CCR10 in T-cell recruitment into the inflamed skin is suggested by a recent observation in delayed-type hypersensitivity. The immigration of T lymphocytes was not appreciably affected by antibodies neutralizing the CCR10 ligand CTACK (CCL27), but complete inhibition was observed when transferred CCR4-deficient T cells were used, suggesting that both receptors are involved concomitantly (Reiss et al. 2001).

CCR9 and its ligand thymus-expressed chemokine (TECK) (CCL25) are implicated in the homing of $\alpha_4\beta_7^+$ T cells to the gut (Zabel et al. 1999; Kunkel et al. 2000). CCR9 is expressed in $\alpha_4\beta_7^+$ T cells, and TECK (CCL25) is produced by epithelial cells of the small intestine, in particular in the crypt region, which is closely associated with the vessels involved in lymphocyte recruitment that express MadCAM-1 (Kunkel et al. 2000; Wurbel et al. 2000). TECK (CCL25) is also detected in small intestine endothelial cells (Papadakis et al. 2001). Several investigations have shown that nearly all T cells in the small intestine express CCR9, underscoring the possible importance of CCR9 and TECK (CCL25) for the lymphocyte traffic in the gut (Zabel et al. 1999; Kunkel et al. 2000; Papadakis et al. 2001).

CHEMOKINES IN DISEASE

The analysis of tissues, exudates, and body fluids by immunochemistry, cytofluorimetry, and in situ hybridization highlights the role of chemokines in infectious and inflammatory pathologies. Receptors for inflammatory chemokines are commonly detected in the lesions of chronic inflammatory diseases, such as rheumatoid arthritis, lupus erythematosus, ulcerative colitis, Crohn's disease, multiple sclerosis, chronic bronchitis, sarcoidosis, and arteriosclerosis. The patterns of expression reflect the peculiarities of the underlying pathology: CCR1, CCR2, CCR5, and CXCR3 are highly expressed in chronic lesions with a predominant infiltration of mononuclear phagocytes and Th1 lymphocytes, CCR3 is enhanced in allergic pathologies with participation of eosinophils and Th2 lymphocytes, whereas CXCR1 and CXCR2 dominate in bacterial infections and acute inflammation. Especially in chronic processes the analysis of receptors and their ligands reveals an apparent redundancy of chemokine involvement in pathology. In animal models, deletions of chemokine or receptor genes and selective receptor antagonists have been used to explore the pathophysiological role of single chemokines and receptors. The issue of chemokine hierarchy in host defense and inflammation, which is highly relevant for the design of therapeutic approaches targeting chemokines, is addressed in a recent review (Gerard and Rollins 2001).

Chemokines and viral infections

Although infections by bacteria and fungi elicit inflammatory responses by inducing chemokine production either directly or on mediation by inflammatory cytokines such as IL-1 and TNF, herpes viruses, pox viruses, and retroviruses have evolved means to subvert the chemokine defense system to their own advantage. The genome of these viruses can encode chemokines, chemokine receptors, structurally unrelated chemokine receptor ligands, and chemokine-binding proteins. These gene products may be expressed on the viral surface or by the cells that the viruses infect. The most impressive case of viral interaction with the chemokine system is the mechanism that enables HIV to enter CD4-bearing

cells. Gp120, a viral envelope protein with no structural similarity to chemokines, binds first CD4 and then a chemokine receptor, usually CCR5 or CXCR4. This interaction exposes the fusogenic extremity of another surface protein, gp41, initiating the fusion of the viral envelope with the membrane of the target cell, which becomes infected. The interaction process leading to fusion and viral entry has not been clarified beyond the definition of the molecules that are necessary on the surface of the virus and the target cell. Several points of contact are assumed between the interacting moieties and formation of aggregates has been suggested, as recently reviewed (Murphy 2001). Co-receptor recognition, the choice between CCR5 and CXCR4, depends on the structure of the variable region of the V3 loop of gp120. In addition to clarifying the mechanism of HIV entry, the discovery of the second binding site, which remained elusive for long after the recognition that CD4 was important, helped to define R5 and X4 HIV strains, which bind CCR5 and CXCR4, respectively, and strains binding to both co-receptors, termed 'R5X4' (Berger et al. 1999). The relevance of chemokine receptors for the infection with HIV is underscored by the observations that individuals with an inactive form of CCR5 (CCR5Δ32) are resistant.

It was reported that gp120, in addition to docking on to CCR5 or CXCR4, also induces signaling (Davis et al. 1997) and thus may contribute to recruitment of additional target cells and/or influence cellular immune defense. A similar interference is ascribed to another HIV protein, the transcription factor Tat, which is released into tissue fluids and has been reported to attract leukocytes bearing CCR2 or CCR3 and to block CXCR4 (Murphy 2001).

Multiple, more direct interferences with the chemokine system were described for human herpesviruses 6 and 8 (HHV6 and 8), and human *cytomegalovirus* (HCMV) which all encode chemokines and chemokine receptors. The receptors have evolved for broad activities and are either constitutively active, similar to ORF74 encoded by HHV8 and expressed in Kaposi's sarcoma (Arvanitakis et al. 1997), or responsive to multiple human chemokines, such as ORF U51 encoded by HHV6 (Milne et al. 2000) and US28 encoded by HCMV (Gao and Murphy 1994). HCMV encodes two CXC chemokines, vCXC1, which is selective for CXCR2, and vCXC2, which has not been characterized (Penfold et al. 1999). The best known viral chemokines vMIP-I, -II, and-III are encoded by HHV8 and interact, as agonist or antagonists, with several CCRs in addition to CXCR4 (Kledal et al. 1997; Stine et al. 2000).

Studies on inflammatory diseases in animal models

In recognition of the inflammatory nature of arteriosclerosis and the importance of monocytes, which infiltrate the arterial wall and progressively transform into macrophages and foam cells (Ross 1999), research has focused on chemokines attracting monocytes. Although, as in other chronic inflammatory conditions, several chemokines are expressed in arteriosclerotic plaques and the underlying arterial wall tissue, deletion of the genes encoding CCR2 in murine models of the disease results in a marked reduction of fatty streak and plaque formation (Boring et al. 1998; Dawson et al. 1999). Remarkably, the pathological process is also attenuated in animals with a deletion of the MCP-1 gene, indicating that other MCPs cannot compensate for the lack of MCP-1 (CCL2) (Gu et al. 1998; Gosling et al. 1999).

The pathology of experimental allergic encephalomyelitis in mice also appears to depend on chemokines acting on mononuclear cells. Deletion of CCR2, the receptor for MCP-1 (CCL2), MCP-2 (CCL8), MCP-3 (CCL7), and MCP-4 (CCL13), protects the animals against the relapsing central nervous system (CNS) inflammation induced by immunization with myelin components (Fife et al. 2000; Izikson et al. 2000), suggesting that monocytes and T lymphocytes, which respond to CCR2 ligands, are particularly important for disease progression. By contrast the development of the disease was not, or only minimally, affected by deleting the genes for MIP-1α (CCL3), RANTES (CCL5), and other chemokines (Gerard and Rollins 2001). These observations suggest that some chemokines, even if expressed in inflammatory lesions, play only a minor role in pathology or act in subordination to other chemokines. This conclusion is supported by studies showing that the encephalomyelitis was not appreciably affected by deletion of the *CCR1* or the *CCR5* genes, suggesting that neither receptor is important for the recruitment of mononuclear cells (Gerard and Rollins 2001). Unfortunately, the role of CXCR3, a receptor that is exclusively expressed in activated T lymphocytes, and its exclusive ligands, Mig, IP10, and I-TAC (CXCL9, -10, and -11, respectively), has not yet been investigated.

Experimental transplantation is a very useful model because of its close relationship to the clinical situation. The introduction of the graft elicits an almost immediate inflammatory response, which is characterized by the expression of IL-8 (CXCL8), MCP-1 (CCL2), and their analogs. This reaction is not related to the specific process of graft rejection and may be induced by inflammatory mediators produced as a consequence of transplant reperfusion (Hancock et al. 2000a). A reaction against the graft follows after the local induction – in the graft and the host tissue – of chemokines, which attract mononuclear cells via CCR1, CCR2, CCR5, and CXCR3. Deletion of any of these receptors retards graft rejection, but the most pronounced effect is observed after deletion of CXCR3 (Gao et al. 2000; Hancock et al. 2000a, b, 2001), confirming that activated $CD4^+$ and $CD8^+$ T cells, which characteristically express high levels

of CXCR3 (M. Loetscher et al. 1996), are essential for the immune reaction leading to rejection. The apparent involvement of CCR1 and CCR2, which are not selective for the effector T-cell population, suggests a role for other players, or simply reflects the concomitant occurrence of an unspecific inflammatory reaction.

An alternate way to assess the role of chemokines in pathology is the use of receptor-blocking agents. In contrast to gene deletion, the intervention with antagonists can be timed at any stage of the pathological process allowing exploration of preventive as well as curative effects. Several models of chronic inflammatory joint diseases, such as the adjuvant-induced arthritis in rats, collagen-induced arthritis in mice, and chronic polyarthritis of the MRL-lpr mouse, are considered as correlates of human rheumatoid arthritis. These models are widely used in the pharmaceutical industry for the assessment of anti-inflammatory drugs, and are of obvious interest for the study of chemokines. Two chemokine receptor antagonists, an amino-terminally truncated MCP-1 (CCL2) (Gong et al. 1997) and Met-RANTES (Met-CCL5) (Plater-Zyberk et al. 1997), were successfully applied in these models to prevent the development of inflammatory lesions and to attenuate the already established disease. These observations confirm the major role of the MCP receptor, CCR2, in the development and maintenance of chronic inflammation, and suggest the involvement of CCR1 and possibly CCR5.

Studies in patients

Despite the frequent, almost obligatory expression of chemokines in diseased tissues, the information about their role in human pathology is rather limited. It follows that the task of chemokine expression studies in human disease is to identify chemokines that are chiefly involved in steering the process of host defense and inflammation for two main reasons: a better understanding of pathogenic mechanisms and the identification of ligands and receptors as targets for therapeutic intervention.

Immunocytochemistry and in situ hybridization of tissue biopsies show that several inflammatory chemokines are usually expressed concomitantly. As chemokines act in the microenvironment of the cells that release them, the study of their potential role in pathology must be based on observations in situ. Discrete evaluation of lesional and nonlesional areas of the same tissue usually discloses important differences and provides a good internal control for the changes occurring in the affected tissues. A random assessment does not take into account the focal nature of inflammation, and measurements of chemokine concentrations in exudates and other body fluids yield only a pale reflection of the disease process. The approach in such investigations may be exemplified by a study of biopsies of inflamed and normal areas of the gut mucosa at different stages of ulcerative colitis (Uguccioni et al. 1999). The local levels of chemokines were quantified by determining the numbers of chemokine-producing cells using image analysis. It was not attempted to quantify the *intensity* of chemokine staining within the cells or in the extracellular space because we found it virtually impossible to obtain reproducible results in standard specimens. Within the lesions, the numbers of cells expressing IL-8 (CXCL8), MCP-1 (CCL2), and MCP-3 (CCL7) were strictly correlated with disease severity, as assessed by clinical criteria, but the frequency of cells producing IL-8 (CXCL8) was about tenfold higher than those producing MCPs. IP10 (CXCL10)-positive cells also increased with pathology, but a significant expression of this chemokine was also observed in nonlesional biopsies, a finding that was not studied further. MIP-1α (CCL3), a chemokine acting via CCR1 and CCR5, was also studied, but no positive cells were detected. These observations indicate that leukocytes bearing CCR2, CXCR1, CXCR2, and CXCR3, i.e. monocytes, activated T cells, and neutrophils, are most likely to be recruited into the lesions, which is confirmed by histology. CCR1 and CCR3, which bind MCP-3 (CCL7), may also be involved in the immigration of mononuclear cells. The redundancy in the expression of inflammatory chemokines is well documented in human disease and animal models. In consideration of the chemokine expression pattern observed in ulcerative colitis, CCR2, the receptor for MCPs, which is expressed in monocytes and all IL-2-activated T cells (Figure 6 and see Figure 4), appears to be of particular relevance.

The only known chemokine receptor defect in humans results from the expression of an inactive variant of CCR5, CCR5Δ32. The defect is relatively frequent in individuals of Caucasian descent who do not present an increased susceptibility to infectious diseases (see 'Chemokines and viral infections' above). Several studies have shown that carriers of the Δ32 allele are partially resistant to chronic inflammatory diseases. It was found that they have a delayed onset of multiple sclerosis (Barcellos et al. 2000). Even homozygotes, however, can develop the disease, indicating that a functional CCR5 is not essential for the occurrence of this particular pathology (Bennetts et al. 1997). In a comparison of about 700 patients with rheumatoid arthritis, 100 patients with lupus erythematosus, and 800 controls, no difference was found in the frequencies of the normal and defective CCR5 allele, but no patient was homozygous for the defective receptor (Gòmez-Reino et al. 1999). Another study of 163 patients with rheumatoid arthritis revealed no difference in the hetero- and homozygous incidence of the CCR5 defect as compared with the healthy population. Carriers of the Δ32 allele, however, showed a tendency to milder disease (Garred et al. 1998).

Svanborg and her colleagues (Frendeus et al. 2000) have studied the role of IL-8 receptor expression for

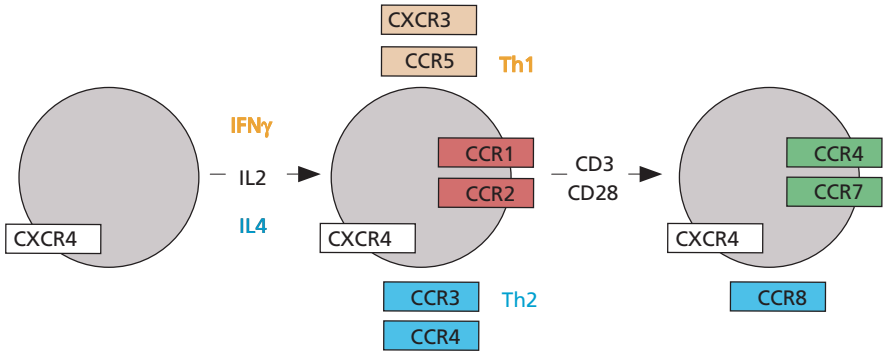

Figure 6 *Chemokine receptor expression in human T lymphocytes. Blood T lymphocytes usually express low levels of chemokine receptors and respond poorly to chemokines. Receptor expression depends on maturation, activation, and differentiation (see text).*

antibacterial defense by comparing the coping of normal and IL-8 receptor-deficient mice with urinary tract infections. The susceptibility of receptor-deficient mice (Godaly et al. 2000; Hang et al. 2000) motivated a study of CXCR1 expression in neutrophils of normal and pyelonephritis-prone children, whose neutrophils were found to have significantly lower CXCR1 levels than those of healthy controls. This observation offers an explanation for the recurrence of pyelonephritis in certain individuals and may lead to the characterization of a genetic polymorphism of CXCR1.

A highly interesting case of chemokine involvement in infection-induced human pathology is documented by a study of chemokine expression in *Helicobacter pylori* gastritis (Mazzucchelli et al. 1999). The comparison of normal and infected mucosa shows that the B-cell-attracting chemokine (BCA-1) (CXCL13) is abundantly and exclusively expressed at the sites of formation of the ectopic follicles, which are characteristic for the disease. The staining for the chemokine coincides with the staining for its receptor, CXCR5, in the immigrated lymphocytes. SLC, by contrast, which is expressed constitutively in the extrafollicular areas of lymphoid tissues together with ELC and is prominent in high-endothelial venules, was not detectable in and around the mucosal follicles, and was restricted to the endothelia of some microvessels. It may have a role in the extravasation of B cells which are then attracted into the ectopic follicles by BCA-1 (CXCL13). Mucosa-associated lymphoid tissue (MALT) lymphomas are a frequent complication of *H. pylori* infection. Interestingly the transformed cells produce high amounts of BCA-1 (CXCL13) and express CXCR5, suggesting that the B-cell-attracting chemokine, in the tumor, may act in an autocrine fashion and influence the proliferation of lymphoma cells. The pathological formation of follicle-like structures was later found to be associated with BCA-1 (CXCL13) expression in Sjögren's syndrome (Amft et al. 2001) and rheumatoid arthritis (Shi et al. 2001) as well.

Luther et al. (2000) have reported the formation of ectopic lymph node-like structures in pancreas islets after expression of BLC, the murine homolog of BCA-1 (CXCL13), in transgenic mice. This study shows that immigrating CXCR5-positive B cells cluster to form follicles. The process of ectopic lymphoid neogenesis, however, goes beyond the accumulation of B cells observed in *H. pylori*-induced gastritis and other human inflammatory diseases. The transgenic animals also express SLC in the parafollicular area leading to the formation of a T-cell zone with high-endothelial venules and lymphotoxin, possibly as a consequence of the exaggerated production of BLC.

CHEMOKINE RECEPTOR ANTAGONISTS

The idea that chemokine antagonists could have therapeutic effects in inflammatory diseases by preventing leukocyte infiltration was proposed soon after the discovery of IL-8 (CXCL8) (Baggiolini et al. 1989). It was then shown that CXCR1 and CXCR2 could be blocked with IL-8 (CXCL8) analogs obtained by truncation or minimal modification of the amino-terminal triggering sequence, and that the same principle could be applied to MCP-1 (CCL2) and RANTES (CCL5) to block the respective CC chemokine receptors (Baggiolini et al. 1994, 1997). The interest in the antagonists grew considerably with the recognition that all chemokines act via heptahelical, Gi-protein-coupled receptors (Murphy et al. 2000) and the discovery that human immunodeficiency viruses bind to chemokine receptors to infect leukocytes and viral entry is prevented by competing chemokines (Berger et al. 1999) and chemokine antagonists (Arenzana-Seisdedos et al. 1996; Simmons et al. 1997). In the same context, chemical substances with known HIV-suppressing activity were tested for chemokine antagonism and it was shown that chemokine receptors could be blocked with small, chemokine-unrelated molecules (De Clercq 2000; Gerlach et al. 2001). These observations boosted the search for nonpeptide chemokine antagonists using high-throughput screening of chemical libraries, with the aim of discovering new drugs for chronic inflammatory diseases.

The hypothesis that antagonists could be effective in the therapy of chronic inflammatory diseases was validated in animal models using amino-terminally modified MCP-1 (CCL2) or RANTES (CCL5). Daily injections of the CCR2 antagonists MCP-1 (9–76), obtained by omission of the first eight amino-terminal residue of synthetic MCP-1 (CCL2), prevented or strongly inhibited the development of the chronic arthritis that arises spontaneously in MRL-lpr mice, and showed considerable anti-inflammatory effects even in animals that had already developed the disease (Gong et al. 1997). Similar preventive and therapeutic effects were observed on repeated injections of Met-RANTES (Met-CCL5) in mice with collagen-induced arthritis (Plater-Zyberk et al. 1997). Met-RANTES also prevented the infiltration of inflammatory cells and significantly reduced vascular injury and tubular damage in renal allografts performed in Lewis RT1 rats (Grone et al. 1999). Met-RANTES is not a true antagonist, because it retains different levels of agonistic activity on the RANTES receptors, CCR1, CCR3, and CCR5 (Proudfoot et al. 1999).

Synthetic, chemokine-unrelated antagonists

The development of chemokine antagonists became a major goal of the pharmaceutical industry. The focus is on receptors that mediate leukocyte infiltration in inflammatory diseases as reflected by the patent applications, which mainly claim activities against CXCR1, CXCR2, CXCR3, CCR1, CCR2, and CCR3. Other, more restricted targets are CXCR4 and CCR5, the two main HIV co-receptors. Several, mostly polycyclic, compounds have been identified in broad screening programs as blockers of single or multiple receptors (Horuk and Ng 2000).

Among the compounds that are ready for studies in patients, the CCR1 antagonist BX471 (Berlex) may soon yield the proof of concept for the use of chemokine antagonists in the therapy of inflammation. It is a potent inhibitor of chemokine activities with K_i values around 1 nmol/l, is apparently selective for CCR1 (Liang et al. 2000), and inactive on adrenergic, muscarinic, dopamine, serotonin, bradykinin, leukotriene B_4 (LTB_4), and neuropeptide receptors. In animal models of disease BX471 was moderately effective in preventing graft rejection in rodents (Horuk et al. 2001b) and was found to act in synergy with the immunosuppressant cyclosporin (Horuk et al. 2001a, 2001b). It also reduced leukocyte infiltration and the development of renal fibrosis after unilateral ureter ligation in mice (Anders et al. 2002). Somewhat related to BX471 is a xanthene derivative, from the Banyu Company, that blocks CCR1 and CCR3. The combination of CCR1 and CCR3 antagonism may be therapeutically desirable for allergic inflammation because both receptors are prominent on eosinophil and basophil leukocytes. Highly selective antagonism for CCR3 was obtained, however, in the same laboratories with benzothiazole derivatives with IC_{50} (concentration of 50 percent inhibition) values for inhibition of binding and function in the low-nanomolar range (Naya et al. 2001; Sabroe et al. 2000). Naphthalene compounds synthesized by Smith Kline Beecham also showed potent blocking effects on CCR3 and only weak interaction with CXCR1, CXCR2, CCR1, CCR7, and the receptors for C5a, C3a, and LTD_4 (White et al. 2000; Dhanak et al. 2001).

Interesting studies were performed with spiropiperidine compounds from Roche (e.g. RS-102895, RS-504393), binding CCR2 but not CCR1, CCR3, or CXCR1 and inhibiting the activity of MCP-1 (CCL2) and its analogs, which are major mediators in chronic inflammatory diseases (Mirzadegan et al. 2000). These compounds were shown to interact with the acidic residue Glu291 at the extracellular end of the seventh transmembrane helix of CCR2, which is important for the high-affinity binding of MCP-1 (CCL2). The compounds, however, were equally or even more potent as blockers for α_1-adrenergic receptors (Mirzadegan et al. 2000), possibly jeopardizing their use as MCP blockers.

In view of their HIV co-receptor function, CCR5 and CXCR4 became prime targets for the development of synthetic antagonists. TAK-799, a compound by Takeda, with high affinity for CCR5 and CCR2 with K_i values of about 1 and 20 nmol/l, respectively, and no effects on CCR1, CCR3, CCR4, and CXCR4 (Baba et al. 1999; Shiraishi et al. 2000) was reported to prevent the binding of the HIV surface protein gp120 by interacting with a cluster of residues at the outer end of the transmembrane helices 1, 2, 3, and 7 of CCR5 (Dragic et al. 2000). CCR5 antagonists without relevant inhibition of CCR2 were synthesized by Ono (Maeda et al. 2001), Schering-Plough (Strizki et al. 2001), and Merck (Finke et al. 2001). Cyclams and bicyclams, on the other hand, are potent antagonists for CXCR4 (De Clercq 2000). Binding-site analysis shows that bicyclams interact with two acidic residues, Asp171 and Asp262, located at the extracellular end of transmembrane domains 4 and 6 of CXCR4, which are both necessary for high-affinity blockade of the ligand-binding pocket (Gerlach et al. 2001).

Missed targets

So far the development of synthetic low-molecular-mass antagonists for CXCR1, CXCR3, and CCR2 has not been as successful. IL-8 (CXCL8), the major ligand for CXCR1, is expressed ubiquitously and most prominently in inflamed tissues, and must be regarded as a primary mediator of neutrophil recruitment in conditions such as infarction and reperfusion, ulcerative colitis, alcoholic hepatitis, early graft rejection, etc., for which CXCR1 antagonists are therapeutically desirable. Antagonists for CXCR3, the receptor for Mig, IP10, and I-TAC

(CXCL9, -10, and -11, respectively) appears equally important, because they would be ideal drugs for preventing the recruitment of activated T lymphocytes in autoimmune diseases and at sites of transplant rejection. Finally the need for selective CCR2 antagonists is underscored by many observations in experimental pathology, including studies on receptor and ligand gene deletions, indicating a primary role for MCP-1 in chronic inflammatory diseases (Gerard and Rollins 2001).

Research and development in this important area of drug discovery have concentrated so far on the search of monoselective compounds. In inflamed tissues, however, one usually observes the concerted expression of several chemokines, suggesting that inhibitors of multiple receptors may be better drugs. Autoimmune inflammation may be treated more efficiently by drugs that block CCR1, CCR2, and CXCR3, rather than with antagonists for a single receptor. Similarly, the combined blockade of CCR1, CCR2, and CCR3 may be the best therapeutic strategy in allergic inflammation. The comparison of the therapeutic efficacy of antagonists for single and multiple receptors in animal models will be useful for directing drug discovery programs.

Natural chemokines as antagonists

Recent observations have shown that some natural chemokines have agonistic as well as antagonistic activities. In a study of chemokines acting on receptors that are differentially expressed in Th1 and Th2 lymphocytes, we found that the agonists for CXCR3, Mig, IP10, and I-TAC (CXCL9,-10, and-11, respectively) are antagonists for CCR3 (Loetscher et al. 2001). They compete for the binding of chemokines to CCR3-bearing cells, and inhibit calcium mobilization and migration induced by CCR3 agonists such as eotaxin-1 (CCL11), eotaxin-2 (CCL24), MCP-2 (CCL8), MCP-3 (CCL7), MCP-4 (CCL13), and RANTES (CCL5). As a result of their dual properties the attractants of Th1 lymphocytes acting via CXCR3 can inhibit the recruitment of Th2 lymphocytes by blocking CCR3, and in this way enhance the polarization of T-cell recruitment. Other natural chemokines with agonistic and antagonistic activities are eotaxin (CCL11), which attracts eosinophils, basophils, and Th2 lymphocytes via CCR3 while blocking CCR2 (Ogilvie et al. 2001), and MCP-3 (CCL7), a potent agonist for CCR1, CCR2, and CCR3 that blocks CCR5 (Blanpain et al. 1999). The inhibition of CCR2-, CCR3-, and CCR5-mediated responses represents a true antagonism as indicated by the fact that binding of the inhibitor does not induce receptor internalization. More work must be done to assess the role of the combination of triggering and inhibiting effects of single chemokines on different receptors, which impresses as a possible mechanism for increasing the selectivity of leukocyte recruitment in disease.

In the 1930s several investigators described the phenomenon of viral interference, whereby the infection of an animal by a virus seemed somehow to protect it against subsequent infection by another virus (Findlay and Mac Callum 1937; Schlesinger 1959; Dianzani 1975). In 1957 Isaacs and Lindenmann (1957; Davies et al. 1982) found an agent of viral interference: a protein, released by cells exposed to a virus, which enabled other cells to resist viral infection. They called it interferon. The great promise of interferon as an antiviral agent was evident from the moment of its discovery, which was supported by an independent report of similar findings by Nagano and Kojima (1958). The promise was enticing because interferon is not directed against any one virus but rather protects cells against a wide range of viruses.

The interferons represent proteins with antiviral activity that are secreted from cells in response to a variety of stimuli (Pestka 1981, 1986; Pestka et al. 1987). There are at least six classes of interferons (IFN): alpha (α), beta (β), gamma (γ), tau (τ), omega (ω), and kappa (κ). The interferons are divided into two groups, designated type I and type II interferons (Pestka et al. 1987). IFN-γ is the only type II interferon whereas the type I interferons consist of five major classes: IFN-α, IFN-β, IFN-ω, IFN-τ, and IFN-κ. There is only one human Hu-IFN-β (Hu-IFN-β), one Hu-IFN-ω, and one Hu-IFN-κ, but a family of multiple IFN-β species exists. It is unlikely that any human IFN-τ exists. IFN-τ was described first as ovine trophoblast protein-1 and is found in ungulates, where it is required for implantation of the ovum (Roberts et al. 1991). Hu-IFN-κ, although it exhibits low specific antiviral activity, is expressed in human keratinocytes (LaFleur et al. 2001).

In general, exposure of human cells to viruses and double-stranded RNAs induces the production of IFN-α and IFN-β species, although IFN-ω and IFN-κ can be produced by appropriate cells. The ratio of IFN-α to IFN-β produced by cells varies with the tissue of origin and the species of the organism. T lymphocytes produce IFN-γ when stimulated with antigens to which they are immune, or when stimulated with mitogens such as staphylococcal enterotoxin A or the combination of phytohemagglutinin and phorbol esters. Most of the interferons in therapeutic use are produced through genetic engineering (Pestka 1981, 1983b, 1986; Pestka et al. 1987). As the first biotherapeutic approved, IFN-α paved the way for the many new biotherapeutics to follow. Nevertheless, we have only touched the surface of understanding the multitude of human interferons.

Many procedures have been described for the partial purification of human and animal interferons (Berg 1982; Pestka 1981, 1983b, 1986; Pestka et al. 1987). Although partial purification of the interferons as bands on a sodium dodecylsulfate–polyacrylamide gel electrophoresis (SDS–PAGE) was reported by a number of groups, it was not until 1978 and thereafter that any

interferon was purified to homogeneity in sufficient amounts for its chemical and physical characterization (Rubinstein et al. 1978, 1979a, 1981; Stein et al. 1980; Friesen et al. 1981). The introduction of reverse phase and normal phase high-performance liquid chromatography (HPLC) to the purification of proteins (Rubinstein et al. 1978, 1979a, 1981; Stein et al. 1980; Friesen et al. 1981) led to the first successful purification of these proteins so that sufficient amounts were available without detergent for their chemical, biological, and immunological studies. Various affinity purification techniques, particularly antibody affinity chromatography were utilized to purify human leukocyte (α) and fibroblast (β) interferons (Knight 1976; Berthold et al. 1978; Cabrer et al. 1979; Zoon et al. 1979; Allen and Fantes 1980; Okamura et al. 1980; Berg and Heron 1981; Kawade et al. 1981; Zoon 1981b; Knight and Fahey 1982; Pestka et al. 1987).

PURIFICATION OF HUMAN LEUKOCYTE INTERFERON α

Since their discovery, many attempts have been made to purify the interferons, with little success until 1978. In fact, interferon used in experiments as well as in initial human clinical trials was essentially a crude protein fraction, less than 1 percent of which by weight consisted of interferon. As a result of the use of such crude interferon-containing material, it was not clear what activities of these preparations were caused inherently by the interferon present and what activities were caused by the numerous other contaminating proteins. By definition, the antiviral activity was the result of the interferon. However, these crude preparations exhibited antiprotozoal and antibacterial activities, inhibited cellular growth (antiproliferative activity), and blocked antibody synthesis, and were ascribed many other activities. However, without purified interferon, it was not possible to demonstrate definitively whether or not a particular activity was the result of the interferon protein molecule itself. Accordingly, it was essential to obtain purified interferon to determine what activities were an inherent part of the interferon molecule. As very little was known about the size and structure of the interferons, the isolation of purified interferons established their chemical composition and structure as well as their biological activities.

Production

We began purification of interferon from human leukocytes in 1977. This interferon was produced by incubating human white blood cells with Newcastle disease virus or Sendai virus for 6–24 h (Familletti and Pestka 1981; Familletti et al. 1981a; Hershberg et al. 1981; Waldman et al. 1981). The procedure was a combination of techniques that have previously been reported (Wheelock 1966; Cantell and Tovell 1971). The antiviral activity was found in the cell culture medium after overnight incubation of the leukocytes as illustrated in Figure 1. We substituted milk casein for human or bovine serum in the culture medium as had been described (Cantell and Tovell 1971). The use of casein, a single protein, instead of serum, which contains many different and uncharacterized proteins, simplified the initial concentration and purification steps. We used leukocytes from normal donors as well as from patients with chronic myelogenous leukemia. These leukemic cells make large amounts of human leukocyte interferon when induced with Newcastle disease virus or Sendai virus (Hadhazy et al. 1967; Lee et al. 1969; Rubinstein et al. 1979a; Familletti et al. 1981a).

The cytopathic effect inhibition assay for interferon as originally described took 3 days. Other assays for interferon were even longer. A more rapid assay was necessary to proceed with the purification expeditiously. A cytopathic effect inhibition assay that could be done in 12–16 h was developed (Familletti et al., 1981b; S. Rubinstein et al., 1981) and accelerated the purification immensely.

High-performance liquid chromatography for protein purification

As classic techniques for protein purification were not successful in the purification of the human interferons,

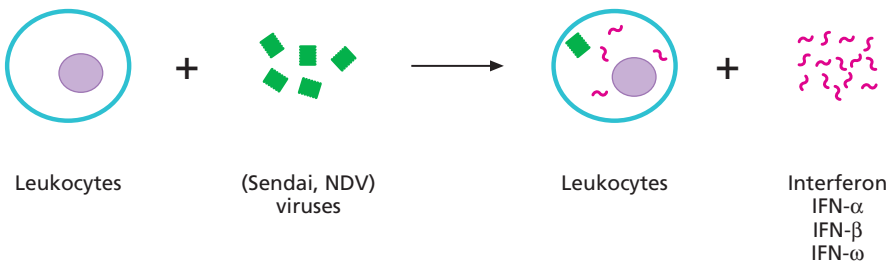

Figure 1 *Production of leukocyte interferon with Newcastle disease virus (NDV) and leukocytes. Leukocytes, the white blood cells of peripheral blood, were obtained from normal donors or patients with chronic myelogenous leukemia. The cells were washed, placed in culture medium with Newcastle disease virus (or with Sendai virus), and incubated overnight at 37°C. Interferon is found in the culture medium after incubation. The cells and virus can be removed by centrifugation, leaving the culture medium containing interferon.*

we applied HPLC to the purification process. Udenfriend and co-workers (Udenfriend et al. 1972; Stein et al. 1973; Bohlen et al. 1975) had developed sensitive fluorescent techniques for detection of amino acids and peptides, and had achieved the separation of peptides by reverse-phase HPLC. However, separation of proteins had not yet been accomplished. In the early experiments, there was uniform failure to achieve any purification of proteins with reverse-phase HPLC because the interferon activity was constantly lost. At the time, increasing the ethanol concentration was used to elute proteins and this was tried for interferon and other proteins without success. It was necessary to use a less polar solvent to elute interferon. Although there was initial hesitancy to use *n*-propanol above 20 percent (v/v) and other organic solvents because of the limited solubility of proteins in such solvents, it was found that *n*-propanol gradients effectively eluted interferon and other proteins without noticeable precipitation at the concentrations employed (Rubinstein et al. 1978, 1979b; S. Rubinstein et al. 1981; Rubinstein and Pestka 1981). Furthermore, by changing the pH of the elution buffer, a completely different separation could be achieved during elution of the same reverse-phase column with *n*-propanol. As subsequently demonstrated with fibroblast interferon, (Friesen et al. 1981) a large number of different columns and solvent systems could be used to effect resolution of proteins. By applying normal-phase chromatography with a diol silica column between the two reverse-phase columns, it was possible to use just three sequential HPLC steps to purify human leukocyte interferon to homogeneity. Sufficient amounts were purified in high yield for initial chemical characterization of the protein and for determination of amino acid composition. The amino acid composition of the human leukocyte interferon species γ2 was the first reported for any purified interferon (Rubinstein et al. 1979b).

The initial steps for purification of IFN included selective precipitations and gel filtration (Figure 2) followed by HPLC. The HPLC steps were reverse-phase chromatography (Figure 3) at pH 7.5 on LiChrosorb RP-8, normal partition chromatography on LiChrosorb Diol (Figure 4), and reverse-phase chromatography at pH 4.0 on LiChrosorb RP-8 (Figure 5). Gradients of *n*-propanol were used for elution of interferon from these columns (Figures 3-5). The overall purification was about 80 000-fold and the specific activity of purified interferon was 2–4 $\times$ 10^8 units/mg (Rubinstein et al. 1979b). Interferon prepared by this procedure yielded a single band of molecular mass (M_r) 17 500 on PAGE. The antiviral activity was associated with the single protein band (Rubinstein et al. 1978). The specific activity of this peak was 4 $\times$ 10^8 units/mg.

Several reports had previously described HPLC of proteins, mainly on ion exchange and size exclusion columns (Chang et al. 1976; Regnier and Noel 1976). However, these systems were either not commercially available or had a low capacity. With proper choice of eluent and pore size, octyl and octadecyl silica could be used for high-resolution reverse-phase HPLC of both peptides and proteins. Accordingly, with *n*-propanol as eluent, the use of LiChrosorb RP-8 (octyl silica) columns for protein fractionation was a major factor in the success of the purification (Figure 5). In addition, LiChrosorb Diol, which is chemically similar to glycophase resins that have been used for exclusion chromatography of proteins, was introduced as a support for normal partition chromatography of proteins (Figure 5b). High recoveries of interferon activity were obtained in each chromatographic step, a requirement when small amounts of initial starting material are present. Although the initial experiments were

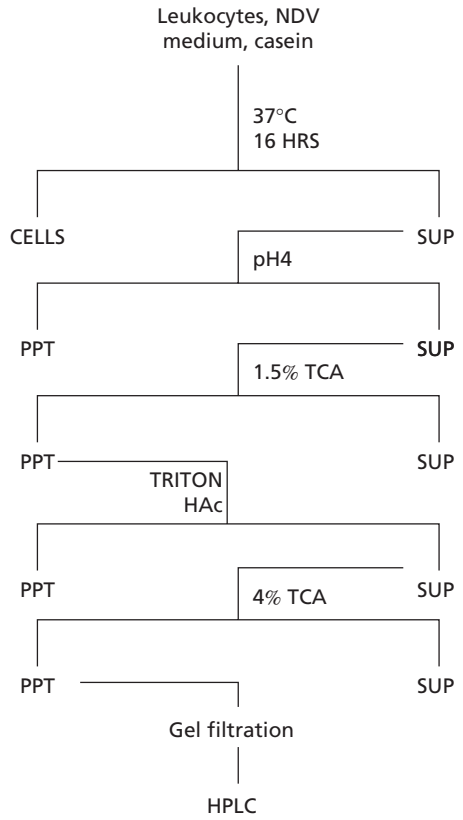

Figure 2 *Flow chart of initial steps in purification of leukocyte interferon. Cells and debris were removed by low-speed centrifugation from the medium containing interferon. Casein was used as a serum substitute. By acidification of the medium to pH 4 with hydrochloric acid, the bulk of the casein, which precipitated, was removed from the interferon, which remained in solution. The interferon was concentrated by two steps involving precipitation with trichloroacetic acid. The concentrated solution containing relatively crude interferon was separated into components of different sizes by gel filtration on Sephadex G-100 in the presence of 4 mol/l urea. Details of these procedures have been described (M. Rubinstein et al. 1979b, 1981a; Familletti et al. 1981a; Hershberg et al. 1981; Waldman et al. 1981). HLPC, high-performance liquid chromatography; NDV, Newcastle disease virus; Ppt, precipitate; Sup, supernatant; TCA, trichloroacetic acid.*

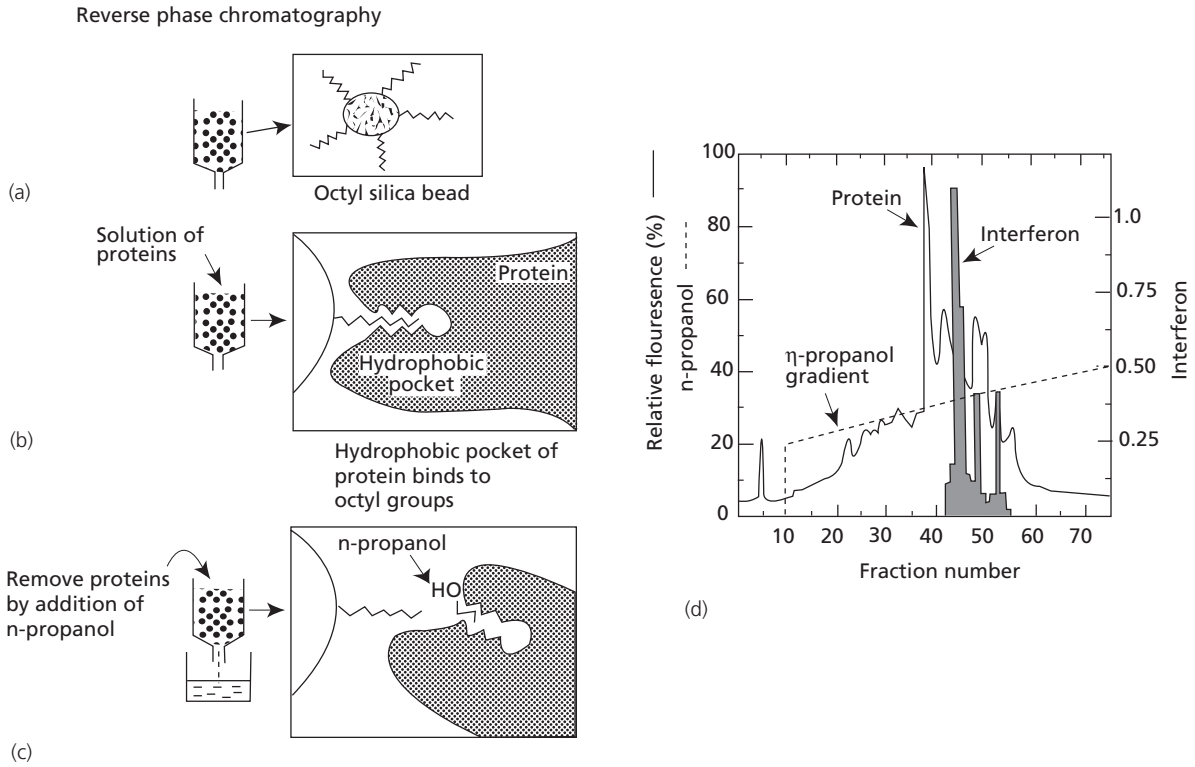

Figure 3 *High-performance liquid chromatography of leukocyte interferon on reverse-phase columns. Columns of porous silica to which octyl groups were bound were used to separate leukocyte interferons from other proteins and to resolve the individual leukocyte interferons. The proteins enter the interstices within the silica particles where the hydrophobic areas of the protein bind tightly to the octyl groups. The nonpolar portion of* n*-propanol can interact with interferon, releasing interferon and other proteins from the column. By eluting the proteins with an increasing gradient of* n*-propanol, the proteins are released in order of their increasing hydrophobicity. Those proteins binding most tightly are released only after high concentrations of* n*-propanol or other appropriate organic solvents are used (Pestka 1983b).*

performed with leukocytes from normal donors (Rubinstein et al. 1978, 1979b), it was found that leukocytes from patients with chronic myelogenous leukemia (CML), who were undergoing leukapheresis to lower their peripheral white blood cell counts, were a rich source of interferon that appeared to be essentially identical to the human leukocyte interferon purified from leukocytes from normal donors (Rubinstein et al. 1979a). As with HPLC of interferon from normal leukocytes on the Diol column (Figure 5b), three major peaks of activity, labeled α, β, γ^2, were observed with interferon prepared from CML cells. (The natural interferons which were isolated from the mixture present in leukocyte interferon by HPLC (Rubinstein et al. 1978, 1979b, 1981; Pestka 1983b) were then designated α1, α2, β1, β2, β3, γ1, γ2, γ3, γ4, γ5, and δ. Unfortunately, the same Greek letters were later used to designate leukocyte, fibroblast, and immune interferons, respectively, as α, β, γ.) Although the protein profiles were almost identical, the activity profiles showed that the amount of activity under peak γ was lower in preparations from leukemic cells compared with normal leukocytes (Rubinstein et al. 1979a, 1979b). However, even from normal leukocytes, the ratio of peaks α, β, and γ varied from one preparation to another. Human lymphoblastoid interferon produced by suspension cultures of Namalva cells was purified by a combination of immunoaffinity chromatography and other methods by Zoon et al. (1979).

The amino acid composition of human leukocyte interferon purified by HPLC as described above (Rubinstein et al. 1979b) shows similarity with human lymphoblastoid interferon (Zoon et al. 1979) and one of the types of mouse interferon (Cabrer et al. 1979). It should be noted that the terms 'leukocyte' and 'lymphoblastoid' interferons simply designate the source of the interferons. The major component of both these preparations consists of Hu-IFN-α species; a minor component of Hu-IFN-β and Hu-IFN-ω is also present in these preparations. As a result of the fact that multiple interferon classes were present in interferons produced from these cell sources, a new nomenclature was proposed to designate the species of interferon rather than the source of the interferon (Interferon Nomenclature 1980). The designation IFN-α was suggested for the major class of interferons present in leukocyte and lymphoblastoid interferon preparations. Hu-IFN-β was the designation for the major interferon produced by human fibroblasts

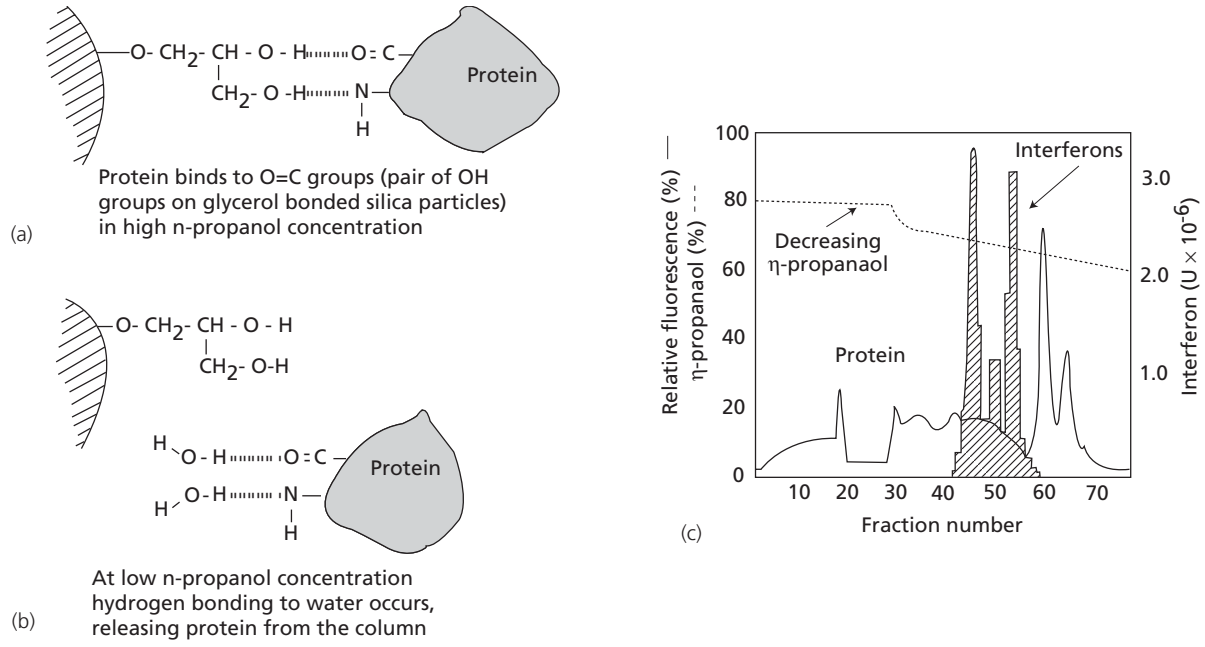

Figure 4 *Hydrogen-bonding high-performance liquid chromatography on diol silica. Hydrogen bonding of proteins to columns containing glycerol covalently attached to silica was used to separate interferon species. As hydrogen bonds are relatively weak bonds and are readily made to the water in which the protein is dissolved, in order to force proteins to bind to the diol silica, it was necessary to use very high concentrations of* n*-propanol. Upon reduction of the* n*-propanol concentration, proteins are released from the column in order of their increasing ability to form hydrogen bonds with the diol groups. Those proteins released first form the weakest hydrogen bonds.* **(a)** *Protein binds to diol groups (pair of OH groups on glycerol-bonded silica particles) in high* n*-propanol concentration.* **(b)** *At low* n*-propanol concentration hydrogen bonding to water occurs, releasing protein from the column. Multiple molecular species of human leukocyte interferon (α, β, and γ) are shown in the figure. These designations should not be confused with the subsequent nomenclature of IFN-α, IFN-β, and IFN-γ assigned to leukocyte, fibroblast, and immune interferons, respectively.*

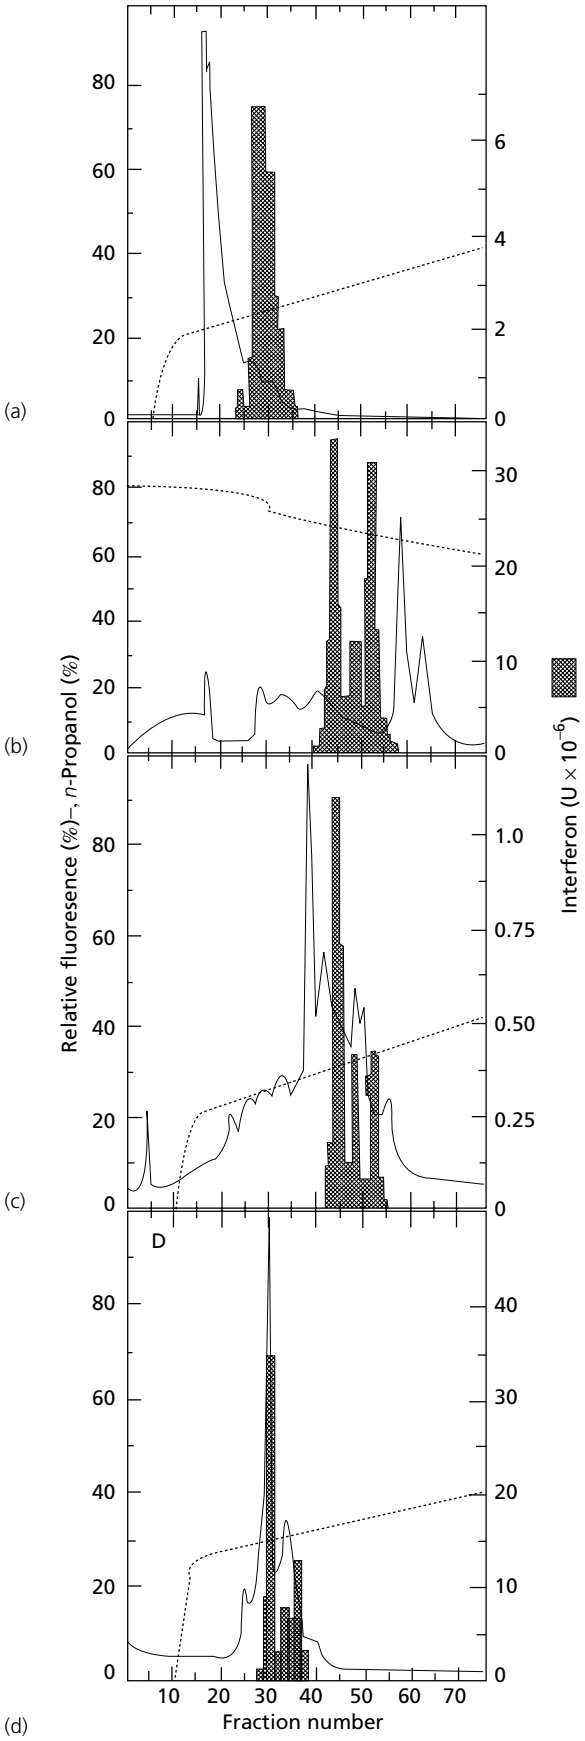
in response to induction with poly(I)·poly(C). Hu-IFN-γ was the designation given for human immune interferon.

Multiple species of leukocyte interferon

During the purification of leukocyte interferon, it became evident that there were multiple species (see Figures 4 and 5). Ten separate species listed as α1, α2, β1, β2, β3, γ1, γ2, γ3, γ4 and γ5 were purified (Table 1). These are all α interferons under the current nomenclature. The designations initially used refer to the peaks obtained on chromatography. It was astonishing at the time, particularly after peptide mapping and sequencing of some of these species, to find a family of proteins that exhibited different activities uncovered (see below).

Human leukocyte interferon is heterogeneous and several bands containing antiviral activity ranging in M_r from 15 000 to 21 000 were observed on SDS–PAGE (Stewart 1974). Heterogeneity of human leukocyte interferon was also observed by isoelectric focusing (Stewart et al. 1977) and several types of chromatographic procedures (Chen et al. 1976; Jankowski et al. 1976; Torma and Paucker 1976; Grob and Chadha 1979; M. Rubinstein et al. 1981). As noted above, our initial work with HPLC revealed three major groups of interferon species that were labeled α, β, and γ according to their order of elution from a LiChrosorb Diol (polar-bonded phase) column (M. Rubinstein et al. 1979b, 1981). These groups were further resolved into several homogeneous components. Although others had reported heterogeneity in crude human leukocyte interferon preparations (Chen et al. 1976; Jankowski et al. 1976; Torma and Paucker 1976; Grob and Chadha 1979), this was not thought to be caused by amino acid sequence heterogeneity. In fact, it had been reported by a number of groups that leukocyte interferon contained carbohydrate and that heterogeneity was the result of differences in the carbohydrate content of the protein (Bose et al. 1976; Bose and Hickman 1977; Bridgen et al. 1977; Stewart et al. 1977). Thus, the well-established heterogeneity of human leukocyte interferon was attributed to differences in the degree of glycosylation. However, five purified species of leukocyte interferon examined contained no detectable carbohydrate: the amino sugar content of each species analyzed (α1, β1, β2, β3, and γ3) was determined to be much less than one residue of either glucosamine or galactosamine per molecule of interferon (M. Rubinstein et al. 1981). Allen and Fantes (1980) also found no carbohydrate on the species of leukocyte interferon that they purified. We therefore concluded that, contrary to the prevailing dogma, human leukocyte interferon is



largely devoid of carbohydrate. Furthermore, because peptide mapping and sequencing revealed significant structural differences among the species, we concluded that leukocyte interferon represents a family of homologous proteins. By analogous procedures, additional leukocyte interferon species were isolated from cultured myeloblasts (Hobbs et al. 1981; Hobbs and Pestka 1982). Since our initial purification, other reports (Allen and Fantes 1980; Berg and Heron 1981; Zoon 1981a, b) have also described multiple species of leukocyte interferon.

Amino acid sequences of leukocyte interferons

As only relatively small amounts of each species were isolated in these early experiments, it was difficult to obtain information about their amino acid sequences. Determinations of the amino acid sequences of the amino-terminal end of human IFN-α were reported (Levy et al. 1980; Zoon et al. 1980), and that of IFN-β as well (Knight et al. 1980; Okamura et al. 1980; Stein et al. 1980; Friesen et al. 1981). It was clear that all the amino acid sequences obtained for human fibroblast interferon were identical and that we all had purified and sequenced the same protein. At the time, it was comforting to know that the new microsequencing procedures were dependable. However, it was striking that the amino-terminal sequences of individual species of human leukocyte interferon were different (Levy et al. 1980; Zoon et al. 1980). The differences confirmed that the leukocyte interferons consisted of a family of closely related proteins. We subsequently isolated a human interferon DNA recombinant (Maeda et al. 1980, 1981; Pestka 1983b), the coding sequence of which was virtually identical to the sequence of one of our purified proteins.

Levy et al. (1981) and Shively et al. (1982) reported amino acid sequences of three species of human leukocyte interferon. Additional sequences were reported by Zoon (1981a). Allen and Fantes (1980) reported the sequences of tryptic fragments obtained from a mixture of several leukocyte interferon species. All these sequences were sufficiently different to establish very clearly the concept of a family of closely related proteins. As described above (Maeda et al. 1980; Pestka 1983b), the first clone of human leukocyte interferon isolated in our laboratory was almost identical in

Figure 5 *High-performance liquid chromatography of interferon. Chromatography on* **(a)** *LiChrosorb RP-8 at pH 7.5;* **(b)** *LiChrosorb diol at pH 7.5; and* **(c)** *LiChrosorb RP-8 at pH 4.0 of the γ peak of part* **(b)**. **(d)** *Rechromatography on LiChrosorb RP-8 of the major activity peak of* **(c)**. *The conditions were similar to those of step* **(c)**. *Several preparations carried through step* **(c)** *were pooled (1.3 × 10⁷ units) and applied to the last column. Table 1 *Human leukocyte interferons first purified*

Species	Molecular mass	Specific activity on bovine MDBK cells (units/mg × 10^{-8})	Specific activity on human AG-1732 cells (units/mg × 10^{-8})
α1	16 500	2.6	2.6
α2	16 200	4	3
β1	16 200	3.4	4.4
β2	16 500	4	2
β3	21 000	4	3
γ1	17 700	2.6	2
γ2	17 700	4	1.5
γ3	17 200	3.5	0.15
γ4	21 000	3.5	4
γ5	16 500	0.9	0.02

Data taken from (M. Rubinstein et al. 1981). The species designations refer to high-performance liquid chromatography peaks not what is now termed IFN-α, IFN-β, and IFN-γ.

sequence to human leukocyte interferon-α2 and interferon-β species, which were, however, 10 amino acids shorter than expected from the DNA sequence. It should be noted that during this time several groups (Iwakura et al. 1978; Kawakita et al. 1978; Maeyer-Guignard et al. 1978; Cabrer et al. 1979; Kawade et al. 1981; Maeyer-Guignard 1981) reported the purification of mouse interferons, and some amino acid sequences were also reported (Taira et al. 1980).

Carbohydrate content

The carbohydrate content of the species of human IFN-α, which were derived from patients with CML and from normal donors, was determined (Labdon et al. 1984). Amino sugar content was measured by HPLC and fluorescamine detection of acid hydrolysates of each sample (Labdon et al. 1984). O-linked glycosylation was also detected by a combination of HPLC, enzymatic analysis, and SDS–PAGE (Adolf et al. 1991). Two species showed significant amounts of glucosamine (Labdon et al. 1984). Most of the purified species of leukocyte interferon from a myeloblast cell line were also tested and two species were found to contain sugar residues. These forms also differed from the CML interferons in that they revealed the presence of greater amounts of galactosamine. The apparent lack of carbohydrate in some of the higher-molecular-mass species of interferon implicated factors other than glycosylation in the molecular-mass differences. The results indicated that some species of IFN-α are glycosylated to various degrees. It was later shown that a natural form of Hu-IFN-α2 was O-glycosylated (Adolf et al. 1991) and that Hu-IFN-ω is glycosylated (Adolf et al. 1990). Considering that the recombinant human IFN-α species produced in *Escherichia coli* do not contain carbohydrate, it was useful to discover that most of the human IFN-α species were devoid of carbohydrate.

PURIFICATION OF HUMAN FIBROBLAST INTERFERON-β

Throughout this chapter, the details focus on Hu-IFN-α because of space limitations. However, sufficient references to the other type I interferons are provided to make the chapter comprehensive.

Native human IFN-β is the major interferon produced by human fibroblasts in response to induction with poly(I)·poly(C) (Havell and Vilcek 1972; Knight 1976; Berthold et al. 1978; Stein et al. 1980; Friesen et al. 1981; Leong and Horoszewicz 1981; Van Damme and Billiau 1981). Figure 6 illustrates the production of IFN-β from human fibroblasts. The media from fibroblasts are collected and the native Hu-IFN-β was partially purified by a number of procedures (Knight 1976; Berthold et al. 1978; Cabrer et al. 1979; Stein et al. 1980; Friesen et al. 1981). It was purified to homogeneity with the use of HPLC (Stein et al. 1980; Friesen et al. 1981). Native IFN-β was found to be glycosylated. The partially purified material was used in initial clinical trials, but only after it was produced by recombinant DNA technology did major clinical trials proceed.

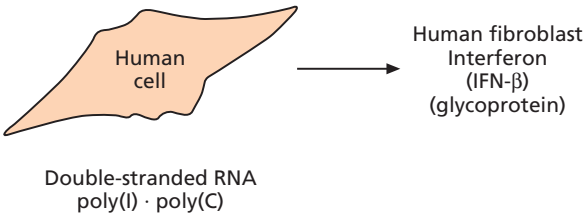

Figure 6 *Production of fibroblast interferon (IFN-β). Human fibroblasts were grown in culture and then exposed to the double-stranded RNA, poly(I)·poly(C), and cycloheximide for about 4 h at which time actinomycin D was added. At about 6 h the medium was replaced to remove the poly(I)·poly(C), cycloheximide, and actinomycin D. The culture fluid containing fibroblast interferon was harvested at 24 h.*

The recombinant human IFN-α species

As recombinant DNA technology offered an opportunity to produce large amounts of Hu-IFNs economically, many scientific teams set out to clone them in bacteria. Several groups achieved the isolation of recombinants for several Hu-IFN-α species (Maeda et al. 1980; Nagata et al. 1980) and for IFN-β (Derynck et al. 1980; Goeddel et al. 1980a; Houghton et al. 1980; Maeda et al. 1980; Taniguchi et al. 1980), arriving at their goals by somewhat different but analogous approaches. The cloning and expression of Hu-IFN-αA as an illustration of these procedures are described.

Isolation of Hu-IFN DNA sequences was a formidable task because it meant preparing DNA recombinants from cellular mRNA that was present at a low level. This task had never been accomplished previously from a protein with an unknown structure. In addition, in order to reconstruct DNA recombinants that would express natural IFN, it is useful to know the partial amino acid sequence of the proteins, particularly at the amino- and carboxy-terminal ends. Without this information synthesis of natural Hu-IFN in bacterial cells would not have been possible. Thus, purification of the Hu-IFNs and determination of their structure (M. Rubinstein et al. 1978, 1979b, 1981b; Zoon et al. 1979; Allen and Fantes 1980; Knight et al. 1980; Levy et al. 1981; Hobbs and Pestka 1982; Shively et al. 1982) assisted us in these efforts.

To isolate recombinants containing the human DNA corresponding to IFN-α, we used a number of procedures. First, it was necessary to isolate and measure the IFN mRNA. This was accomplished several years earlier when IFN mRNA was translated in cell-free extracts (Pestka et al. 1975; Thang et al. 1975) and in frog oocytes (Reynolds et al. 1975; Cavalieri and Pestka 1977; Cavalieri et al. 1977a, 1977b). The next step was to prepare sufficient mRNA from cells synthesizing IFN, and this was accomplished with both fibroblasts and leukocytes (Familletti et al. 1981a; McCandliss et al. 1981a). A library of complementary DNA (cDNA) was prepared from a template of partially purified mRNA isolated from human leukocytes synthesizing IFN. The next and hardest part of the procedure was to find in this vast library of recombinant plasmids those that contained DNA encoding IFN. We devised an indirect two-stage procedure to identify clones containing interferon sequences. In the first stage, we screened all the bacterial colonies to find those with cDNA made from the RNA of induced cells; among these there might have been some carrying IFN cDNA. We therefore screened all the recombinants for their ability to bind to mRNA from cells synthesizing IFN (induced cells), but not to mRNA from uninduced cells (those not producing IFN). To do this, individual transformant colonies were screened by colony hybridization for the presence of induced, specific sequences with ^{32P}-labeled IFN mRNA (mRNA from induced cells) as the probe. In the presence of excess mRNA from uninduced cells, recombinants that were representative of mRNA sequences existing only in induced cells should be evident on hybridization. This screening procedure allowed us to discard about 90 percent of the colonies: as their plasmids carried no induced cDNA, these could not encode IFN (Maeda et al. 1980, 1981).

In the second stage, we identified those recombinants containing the IFN DNA sequences among the remaining 10 percent. To do this, we pooled the recombinant plasmids in groups of 10 and examined these for the presence of IFN-specific sequences by an assay that depends on hybridization of IFN mRNA to plasmid DNA (Maeda et al. 1980; McCandliss et al. 1981b). Plasmid DNA from 10 recombinants was isolated and covalently bound to diazobenzyloxymethyl (DBM) paper. The mRNA from induced cells was hybridized to each filter. Unhybridized mRNA was removed by washing. After the specifically hybridized mRNA was eluted, both fractions were translated in *Xenopus laevis* oocytes. Once a positive group had been found (one in which the specifically hybridized mRNA yielded IFN after microinjection into frog oocytes), it was necessary to identify the specific clone or clones containing IFN cDNA. The 10 individual colonies were grown, the plasmid DNAs were prepared, and each individual DNA was examined by mRNA hybridization as above. By these procedures a recombinant, plasmid 104 (p104), containing most of the coding sequence for a Hu-IFN-α was identified (Maeda et al. 1980). The DNA sequence was determined and found to correspond to what was then known of the amino acid sequence of purified Hu-IFN-α (Levy et al. 1980, 1981). The cDNA insert in p104 contained the sequence corresponding to more than 80 percent of the amino acids in IFN-αA, but not for those at its amino-terminal end. It was, therefore, used as a probe for finding a full-length copy of the IFN cDNA sequence which could be used for expression of Hu-IFN-αA in *E. coli*. In addition, p104 DNA was used to isolate DNA sequences corresponding to other IFN-α species directly from a human gene bank.

Examination of the coding regions of the IFN-α genes that were isolated in our laboratory and others have shown that these correspond to a family of homologous proteins, the IFN-α species (Rubinstein et al. 1979b; Pestka 1983b), which are closely related to each other and yet each is unique in its amino acid sequence. Thus, the previously discovered heterogeneity in Hu-IFN-α was shown to be at least in part the result of distinct genes representing each expressed Hu-IFN-α sequence. The cloned Hu-IFN-αA, which was the first one that we isolated, corresponds to the natural Hu-IFN-α species which we purified from the mixture present in IFN-α by HPLC and termed α2 (see above). By similar proce-

dures to those described for 104, p101 was shown to contain the sequence for Hu-IFN-β (Maeda et al. 1980). Thus, the nucleotide sequences coding for Hu-IFN-α and Hu-IFN-β were identified.

The recombinant human IFN-α genes and proteins

A summary of the IFN-α genes and proteins reported is given in Table 2. There are in essence 14 human genes that comprise the IFN-α family. Minor variants consisting of one or two amino acid differences account for the multiple alleles (Pestka 1983a, 1983b, 1986; Diaz et al. 1994). Excluding the pseudogene *IFNAP22*, there are 13 genes. One of them, *IFNA10* is also a pseudogene in one allelic form. There are 13 proteins expressed from these genes. The protein produced from gene *IFNA13* is identical to that produced from *IFNA1*. Thus, there are 12 separate IFN-α proteins (and allelic forms) produced from these 14 genes (Table 2).

ACTIVITIES OF THE PURIFIED IFN-α SPECIES

After purification of the IFN-α species, we determined their activities (see Table 1). It was evident that each interferon species exhibited a distinct profile of antiviral activity (AV) on human AG-1732 and bovine MDBK cells (Evinger et al. 1980a, b, 1981; Pestka et al. 1980a, b; Evinger and Pestka 1981; S. Rubinstein et al. 1981). The overall ratios varied over a range of 200-fold. This presaged the idea that each IFN-α species had a different activity profile. When the profile of activities was expanded to evaluate antiproliferative activity (AP) (Table 3) and natural killer (NK) cell stimulatory activity (Table 3), it was observed that there was no clear correlation among the activities. Thus, the IFN-α family represents related and homologous proteins each exhibiting a unique activity profile. This is illustrated further below.

Table 2 *Human interferon α genes (14) and proteins (12/13)*

Genes	Proteins
IFNA1	IFN-αD, IFN-α1
IFNA2	IFN-αA (IFN-α2a), IFN-α2 (IFN-α2b), IFN-α2c
IFNA4	IFN-α4a (IFN-α76), IFN-α4b
IFNA5	IFN-αG, IFN-α5, IFNα61
IFNA6	IFN-αK, IFN-α6, IFN-α54
IFNA7	IFN-αJ, IFN-αJ1, IFN-α7
IFNA8	IFN-αB2, IFN-αB, IFN-α8
IFNA10	IFN-αC, IFN-α10, IFN-αL, IFN-α6L
IFNA13	IFN-α13 (sequence identical to IFN-α1)
IFNA14	IFN-αH, IFN-αH1, IFN-α14
IFNA16	IFN-αWA, IFN-α16,IFN-αO
IFNA17	IFN-αI, IFN-α17, IFN-α88
IFNA21	IFN-αF, IFN-α21
IFNAP22	IFN-αE

Table 3 *Relative activities of human leukocyte interferons*

Species	AV	AP	NK
α_1	59	22	Low
α_2	68	12	Low
β_1	100	ND	Low
β_2	45	100	High
β_3	68	6	High
γ_1	45	12	High
γ_2	34	47	Low
γ_3	3.4	16	Low
γ_4	91	5	Low
γ_5	0.45	75	Low

AV, relative antiviral activity; AP, relative antiproliferative activity; NK, relative natural killer cell activity; ND, not done. The activities are relative, with the value 100 arbitrarily set for the interferon with the highest activity.

After the production and purification of the recombinant IFN-α species, a number of activities were determined. The sequences of various IFN-α species were described (Goeddel et al. 1980b; Goeddel and Pestka 1982, 1989; Henco et al. 1985). As can be seen in Table 4, the hybrid IFN-αA and IFN-αD molecules vary markedly in their AV, AP, and NK cell activity (Herberman et al. 1982a; Ortaldo et al. 1982, 1983a, 1983b, 1984; Rehberg et al. 1982). It is possible to change radically the properties of an interferon by making hybrids and generate properties that neither one of the parental molecules exhibits, e.g. the hybrid Hu-IFN-αA/D (*Bgl*) constructed from IFN-αA and IFN-αD exhibits high activity on mouse cells, a property neither of the parental molecules exhibits (Rehberg et al. 1982). As with the natural IFN-α species, the ranges in the activity ratios vary about 100-fold among the hybrid species (Table 4). A hybrid between Hu-IFN-αB2 (α8) and Hu-IFN-αD (α1) was constructed (called Hu-IFN-αB/D) and tested in humans with results comparable to the approved recombinant interferons (Gangemi et al. 1989; von Wussow et al. 1991; Hochkeppel et al. 1992; Ritch et al. 1992; Schellekens et al. 1996). Consensus IFN (IFN-con1) is a synthetic, non-naturally

Table 4 *Ratio of specific molecular activities*

IFN-α	AV/AP	AV/NK
A	0.38	41
D	0.80	1.3
A/D (*Bgl*)	0.59	95
A/D (*Pvu*)	0.14	3.2
D/A (*Bgl*)	1.7	6.0
D/A (*Pvu*)	0.14	13
A/D/A	0.60	1.8

AV, relative antiviral activity; AP, relative antiproliferative activity; NK, relative natural killer cell activity.

Table 5 *Effect of interferons on human natural killer (NK) cell activity*

	IFN-α (units/ml)
αA, α2	2
αB, α8	1
αC, α10	2
αD, α1	7
αF, α21	89
αI, α17	11

αK, α6	29

The values in the table represent the concentration for 50 percent stimulation of natural killer cell activity. Data from Ortaldo et al. (1984).

occurring IFN-α hybrid designed by assigning each of the most frequently observed amino acids appearing at each position in the Hu-IFN-α subtypes (Klein et al. 1988). For the most part it is almost a hybrid between IFN-αA and IFN-αF with only five differences, several of which were introduced for purposes of cloning. As a result of the large number of amino acid differences between the hybrid IFN-α species and the naturally occurring IFN subtypes, there is the potential for greater immunogenicity than with the natural IFNs in long-term treatment. However, clinical studies with both the IFN-αB/D and IFN-αCon1 molecules suggests that immunogenicity is not a significant problem. Among the normal IFN-α species (Table 5), the individual species differ by over 10 000-fold in NK activity alone (Ortaldo et al. 1983a, 1984). IFN-αJ (IFN-α7) exhibits virtually no NK activity (Table 5) and can act as an antagonist of NK activity, blocking other IFN-α species from stimulating NK cells (Ortaldo et al. 1984).

FUNCTIONAL UNIT OF IFN-α

As we did not know whether IFN-α functioned as a monomer or a dimer, we used electron bombardment to determine the functional unit (Pestka et al. 1983; Kempner and Pestka 1986). The results are summarized in Figure 7. The functional unit of IFN-α was shown to be a monomer, whether the species were produced in *E. coli* or by human leukocytes (Pestka et al. 1983; Kempner and Pestka 1986). The functional unit of IFN-β appears to be a dimer (Pestka et al. 1983; Kempner and Pestka 1986) whereas that of IFN-γ was shown to be a tetramer (Pestka et al. 1983; Kempner and Pestka 1986; Langer et al. 1994). One crystal structure of human IFN-α2b suggested a dimer structure (Radhakrishnan et al. 1996). However, the solution structure is consistent with a monomer (Klaus et al. 1997). These results need to be understood in terms of the receptor–ligand interaction. The structural results suggest that IFN-α and IFN-β interact with the receptor differently,

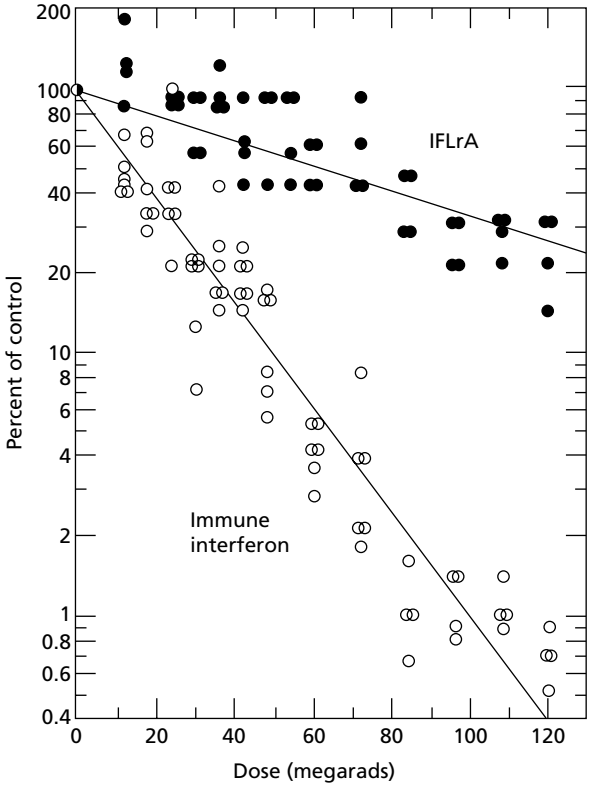

Figure 7 *Electron bombardment of recombinant human leukocyte (Hu-IFN-αA) and immune (IFN-γ) interferons. Data from Batcheler et al. (1986) and Fish et al. (1986). The molecular weight estimates for the functional units of the recombinant proteins are as follows: IFN-αA, 20 000; IFN-γ, 73 000. The monomer molecular masses are: IFN-αA, 19 219; IFN-γ, 17 126.*

which will very probably explain some of their functional differences.

General remarks

The IFN-α family consists of 13 expressed alleles producing 12 different proteins that exhibit remarkably different activity profiles. For the most part, the IFN-α species are not glycosylated although some contain carbohydrate. The recombinant proteins produced in *E. coli* have properties essentially equivalent to the proteins produced by human cells. Predominantly, only one recombinant IFN-α protein is used therapeutically (IFN-α2a, IFN-α2b, and IFN-α2c, allelic variants) so that the remaining IFN-α species remain an untapped reservoir of opportunity. Why the body produces so many of these interferons is an unanswered question. As our understanding of the mechanism of their receptor interactions develops, some of these answers should be forthcoming.

Although purification of the interferons to homogeneity remained elusive for about two decades after their discovery, they are now available in purified form. The largest amounts available are the species

produced in *E. coli*. For purification, immunoaffinity chromatography has proved to be generally useful both on a laboratory and on a commercial scale. Nevertheless, techniques other than immunoaffinity chromatography have also proved to be successful. The availability of these proteins for laboratory and clinical studies has already catalyzed extensive new developments with them. The interferons are approved therapeutic agents worldwide. As the understanding of these agents becomes more extensive, we will gain new insights into their actions and develop new applications for their use.

RECOMBINANT HUMAN IFN-β

There is only one human IFN-β gene. The IFN-β was cloned by a number of laboratories (Derynck et al. 1980; Goeddel et al. 1980a; Houghton et al. 1980; Taniguchi et al. 1980) and expressed in *E. coli* and in eukaryotic vectors for expression in mammalian cell such as mouse or Chinese hamster ovary (CHO) cells (Canaani and Berg 1982; Zinn et al. 1982; Higashi et al. 1983; Maroteaux et al. 1983). IFN-β is active when expressed with or without carbohydrate. Similar to IFN-α, IFN-β exhibits antiviral and antiproliferative activity. The major use of IFN-β has been in the treatment of multiple sclerosis (Keegan and Noseworthy 2002), but the mechanisms by which it functions to ameliorate this disease are far from understood.

INTERFERON RECEPTORS

As noted above, the interferons are divided into two groups designated type I (IFN-α, IFN-β, IFN-κ, IFN-ω, and IFN-τ) and type II (IFN-γ) (Pestka 1981, 1986, 1997; Pestka et al. 1987; LaFleur et al. 2001). The past and current designations of the interferons are given in Table 6. Although leukocyte and fibroblast interferons were the original designations based on the source of the interferons, they usually consisted of multiple components dependent on the method of production. In general, leukocyte interferon obtained from white blood cells predominantly contained IFN-α species, but small quantities of IFN-β and IFN-ω were also present. Human fibroblast interferon consisted of IFN-β when induced by poly(I)·poly(C), but contained both IFN-α and IFN-β when induced by viruses, although IFN-β was predominant.

Similar to most cytokines and growth factors the actions of interferons are mediated by interaction with specific cell-surface receptors and the Jak–Stat signal transduction pathway (Aguet 1980; Lengyel 1982; Pestka et al. 1987; Langer and Pestka 1988; Sen and Lengyel 1992; Darnell et al. 1994; Uzé et al. 1995), although other pathways are increasingly being delineated (Raz et al. 1994; Durbin et al. 2000; Dalod et al. 2002). Competition binding studies demonstrated that type I IFNs share the same receptor complex, whereas type II IFN (IFN-γ) binds to a distinct receptor (Branca and Baglioni 1981; Pestka et al. 1987; Langer and Pestka 1988; Flores et al. 1991; Li and Roberts 1994; Alexenko et al. 1995). Components of both these classes of receptors were cloned. With the cloning of the receptor components, the mechanism of interferon action and the resultant signal transduction events were delineated in remarkable detail. Two transmembrane chains of the type I receptor complex (Uzé et al. 1990; Cleary et al. 1992, 1994; Domanski et al. 1995; Novick et al. 1994; Soh et al. 1994c; Lutfalla et al. 1995; Cook et al. 1996) and two chains of the type II receptor complex (Rashidbaigi et al. 1986; Jung et al. 1987; Aguet et al. 1988; Gray et al. 1989; Hemmi et al. 1989, 1994b; Kumar et al. 1989; Munro and Maniatis 1989; Cofano et al. 1990; Soh et al. 1993, 1994a) were characterized and cloned. As the IFN-γ–receptor complex (type II) has been characterized much better than the type I interferon–receptor complex, the IFN-γ receptor is discussed as a preface to the type I receptor. Understanding of the molecular events from ligand binding to signal transduction has elucidated several new paradigms that provide a basis for understanding the family of multichain cytokine receptors and the specificity of signal transduction. The IFN-γ–receptor complex has thus provided the basic model for other members of the family of class II cytokine receptors including the type I interferon and interleukin (IL) 10 receptor complexes.

Table 6 *Classes of interferons*

Original designation	Greek name	Current designation	Type
Leukocyte	Alpha	IFN-α	Type I
Fibroblast	Beta	IFN-β	Type I
Leukocyte (II)	Omega	IFN-ω	Type I
Keratinocyte	Kappa	IFN-κ	Type I
Trophoblast	Tau	IFN-τ	Type I
Immune	Gamma	IFN-γ	Type II

Receptor nomenclature

The designations of the interferon receptor components are given in Tables 7 and 8. These receptor complexes consist of two or more components. It also appears that the individual components may contribute to one extent or another to ligand binding so that designations such as an α subunit for the ligand-binding component and the β subunit for the signal transduction subunit are not warranted. The subunits are named in the order in which they were cloned and discovered as distinct entities. Alternate designations for the subunits that have been used are also given (Tables 7 and 8).

THE TYPE II INTERFERON (IFN-γ) RECEPTOR

Chromosomal localization of the IFN-γ receptor ligand-binding chain and discovery of two chains required for activity

It was shown by study of ligand-binding competition that the IFN-γ receptor was distinct from that of the receptor that bound IFN-α and IFN-β (Branca and Baglioni 1981). Through somatic cell genetic techniques, Rashidbaigi et al. (1986) demonstrated that the gene for the ligand-binding chain of the human IFN-γ receptor was localized to human chromosome 6 (specifically 6q). Nevertheless, although somatic cell hybrids that contain this region of, or the entire, chromosome 6 exhibited excellent binding of IFN-γ, the ligand was unable to initiate any biological activities. This study led Jung et al. (1987, 1988) to the discovery that an additional component located on human chromosome 21 (specifically 21q) was required for function through the IFN-γR1 chain encoded on human chromosome 6. Thus, two species-specific components were involved as part of the functional IFN-γ receptor: the ligand-binding chain of the receptor, IFN-γR1; and the second chain of the receptor, IFN-γR2, we initially designated accessory factor-1 (AF-1) that is required for signal transduction through the receptor. These somatic cell genetic experiments led to the discovery of the location of the ligand-binding chain (IFN-γR1) to chromosome 6 and the location of the second chain, IFN-γR2, to human chromosome 21 and set the stage to isolate and clone these components. The comparable mouse chains were localized to mouse chromosomes 10 and 16, respectively (Mariano et al. 1987, 1996). Tables 7 and 8 summarize the suggested nomenclature for these chains.

Subsequent to the localization of the ligand-binding chain, both the human (Aguet et al. 1988) and mouse (Gray et al. 1989; Hemmi et al. 1989; Kumar et al. 1989; Munro and Maniatis 1989; Cofano et al. 1990) IFN-γR1 chains were cloned and shown to bind ligand. In addition, these studies confirmed our observations that the ligand-binding component was insufficient for generating a biological response. To generate a biological response, it was necessary to have the ligand-binding chain plus the second chain IFN-γR2 (AF-1). It should be noted that the biological response measured in these assays was induction of class I major histocompatibility complex (MHC) antigen expression. By reconstituting functional activity with the cloned Hu-IFN-γR1 and human chromosome 21, it was definitively demonstrated that the ligand-binding chain was the necessary and sufficient component contributed by human chromosome 6 (Jung et al. 1990). It was thus concluded that the functional receptor consisted of two chains, which are now designated IFN-γR1 and IFN-γR2 (see Table 7).

Study of chimeric human and mouse IFN-γR1 chains demonstrated that the ability of mouse and human IFN-γ species to stimulate MHC class I antigen induction in various cells transfected with the chimeric receptors required the homologous extracellular domain of the receptor, e.g. the chimeric receptor HMM (human extracellular, murine transmembrane, and murine intracellular domains, respectively) was able to respond to Hu-IFN-γ only in mouse cells or hamster cells containing human chromosome 21 or 21q (Gibbs et al. 1991; Hemmi et al. 1992; Hibino et al. 1992; Kalina et al. 1993). Modification of the mouse IFN-γR1 chain by

site-specific mutation was reported by Lai (1994) to yield an interesting ectodomain mutant chain (His196-Ala) that was able to bind ligand, but was not able to support signal transduction as measured by MHC class I antigen induction, growth inhibition, or activation of Stat1α. This appears to be the first ectodomain mutant that alters signal transduction, but not ligand binding. It should provide some interesting insight into how this His196 of the IFN-γR1 chain is involved in supporting signal transduction. Perhaps, this region of the receptor is required for interaction with the IFN-γR2 chain.

The IFN-γR1 chain

The IFN-γR1 chain serves to bind ligand. The functional architecture of the IFN-γR1 intracellular domain is concentrated in two specific regions. Distal from the membrane, a five-residue sequence (Y^{457}DKPH^{461}) is required for all signal transduction (Cook et al. 1992; Farrar et al. 1991, 1992). This sequence is completely conserved in human and mouse receptors. Y^{457} is phosphorylated on ligand binding, and serves as a recruitment site for Stat1α (Greenlund et al. 1994). The function of the other residues in the YDKPH motif are not known, but D^{458} and H^{461} are required (Cook et al. 1992; Farrar et al. 1992). Specific mutations have shown that the carboxy-terminal 29 amino acids have no apparent function (Cook et al. 1992). A membrane-proximal L^{266}PKS^{269} motif is required for receptor activity and Jak-1 binding (Kaplan et al. 1996).

The second receptor chain (IFN-γR2)

The second chain of the IFN-γ receptor was isolated by Soh et al. (1993, 1994a); Cook et al. (1994), and Hemmi et al. (1994b). The cDNA clones encode the necessary species-specific factor and are able to substitute for human chromosome 21 to reconstitute the Hu-IFN-γ receptor-mediated induction of class I HLA antigens. However, the factor encoded by the cDNA does not confer full antiviral protection against encephalomyocarditis virus (EMCV), suggesting that an additional factor encoded on human chromosome 21 may be required for reconstitution of antiviral activity against EMCV (Soh et al. 1993, 1994a; Cook et al. 1994; Lembo et al. 1996). Similar observations were made with the mouse IFN-γR1 and IFN-γR2 chains. Substitution of each of the tyrosine residues of the intracellular domain by phenylalanine did not alter the ability of the mouse IFN-γR2 chain to support signal transduction (Hemmi et al. 1994a). Kotenko et al. (1995) showed that the intracellular domain of the Hu-IFN-γR2 chain lacking the terminal 49 residues was totally inactive in MHC class I antigen induction, Jak1 and Jak2 phosphorylation, Stat1α activation, and tyrosine phosphorylation of the IFN-γR1 chain. Furthermore, cells expressing the Hu-IFN-γR2 chain alone did not crosslink or bind ligand; however, when both Hu-IFN-γR1 and Hu-IFN-γR2 chains were co-expressed in hamster cells, the association constant for binding of ligand increased about threefold and a specific band of a crosslinked Hu-IFN-γ–Hu-IFN-γR2 complex was observed (Kotenko et al. 1995). This indicated that the two chains of the receptor must be in close proximity as suggested by experiments with chimeric receptors noted above. Jak2 was found to associate with the IFN-γR2 intracellular domain (Kotenko et al. 1995). Residues 263–267 and 270–274 of the intracellular domain of IFN-γR2 act as a Jak2-binding site (Bach et al. 1996). The cytoplasmic domains of the IFN-γR2 subunits, similar to the cytoplasmic domains of the IFN-γR1 chains, can be interchanged between species with no loss of biological activity, confirming that the species-specific interaction of the IFN-γR1 and IFN-γR2 chains involves only the extracellular domains of the two proteins (Muthukumaran et al. 1996).

The functional IFN-γ receptor complex

A model for the functional IFN-γ receptor is shown in Figure 8. The IFN-γR1 chains bind the ligand whereas the IFN-γR2 chains serve to complete the complex for signal transduction.

Specificity of ligand binding

There are two distinct interactions that underlie species specificity: the binding of ligand to the IFN-γR1 chain, and the interaction of the IFN-γR1 and IFN-γR2, independent of ligand. The interaction of IFN-γ with the IFN-γR1 chain is highly species specific. Human IFN-γ stimulates no activity on rodent cells whatsoever, and rodent IFN-γ exhibits no activity on human cells. This effect is attributed to the interaction of the ligand with the IFN-γR1 chain. The presence of the second chain IFN-γR2 may increase the overall affinity of the ligand to the receptor complex slightly (Lai 1994; Kotenko et al. 1995; Marsters et al. 1995).

Specificity of the interactions of the two chains

Chimeric receptors were constructed between the mouse and human IFN-γR1 chains (Gibbs et al. 1991; Hemmi et al. 1992; Hibino et al. 1992; Kalina et al. 1993). The extracellular, transmembrane and intracellular domains were swapped between the human and mouse IFN-γR1 chains. The chains were introduced into mouse–human and hamster–human somatic cell hybrids that contained human chromosome 21, which expressed the Hu-IFN-γR2 chain. These results established that the extracellular domains of the two chains must be matched from the same species to enable the ligand to initiate signal transduction.

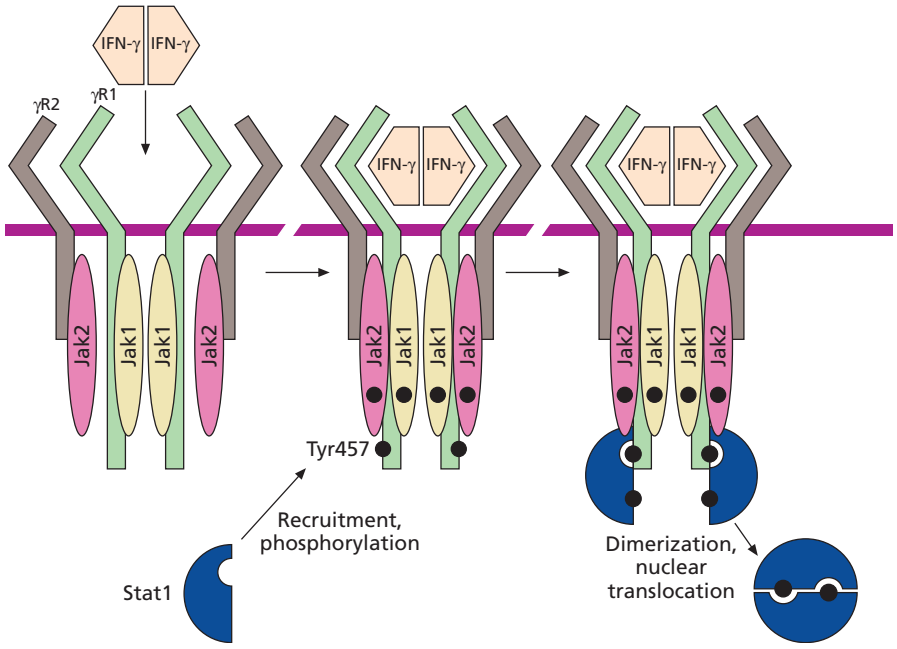

Figure 8 *Model of the IFN-γ receptor complex and signal transduction. In the three-dimensional structure it is likely that the extracellular domains of both IFN-γR1 and IFN-γR2 chains contact the ligand, IFN-γ.*

In a complementary series of experiments with hamster–mouse somatic cell hybrid cells, it was shown that mouse IFN-γ could activate the hybrid cells only when the mouse chromosome 16 was present in the hybrids and the IFN-γR1 chain contained the extracellular mouse domain of this chain (Hibino et al. 1992; Mariano et al. 1996).

Specificity of signal transduction

Each cytokine that utilizes the Jak–Stat signal transduction pathway activates a distinct combination of members of the Jak and Stat families. Thus, the Jaks, the Stats, or both could contribute to the specificity of ligand action. With the use of chimeric receptors involving the interferon-γ receptor (IFN-γR) complex as a model system, Kotenko et al. (1996) demonstrated that Jak2 activation is not an absolute requirement for IFN-γ signaling. Other members of the Jak family can functionally substitute for Jak2. IFN-γ can signal through the activation of Jak family members other than Jak2 as measured by Statlα homodimerization and MHC class I antigen expression (Figure 9). This indicates that Jaks are interchangeable in the Jak–Stat signal transduction pathway. The necessity for the activation of one particular kinase during signaling can be overcome by recruiting another kinase to the receptor complex (Figure 9). The results suggest that the Jaks do not contribute significantly to the specificity of signal transduction.

The Stats represent proteins containing -SH_2, -SH_3, and DNA-binding domains (for reviews, see Darnell et al. 1994; Fu 1995). The highly selective and specific interaction between Stat -SH_2 domains and the phosphotyrosine-containing Stat recruitment sites on the intracellular domains of the cytokine receptors determines which Stats are to be recruited to a particular receptor complex (Heim et al. 1995; Stahl et al. 1995). Thus, the major specificity of the pathway probably results in large part from the specificity of the Stat recruitment sites on the receptor chains. Other molecules that interact with Jaks and Stats may contribute to the specificity and range of the interaction (Pollack et al. 1995; Collum et al. 2000).

Rationale for the multichain receptor

In the current model, binding of IFN-γ causes oligomerization of the two IFN-γ receptor (IFN-γR) subunits, receptor chain 1 (IFN-γR1, the ligand-binding chain) and the second chain of the receptor (IFN-γR2), and causes activation of two Jak kinases (Jak1 and Jak2) as illustrated in Figure 8. In contrast, the erythropoietin receptor (EpoR) requires only one receptor chain and one Jak kinase (Jak2). Chimeras between the EpoR and the IFN-γR1 and IFN-γR2 chains demonstrated that the architecture of the EpoR and the IFN-γR complexes differs significantly (Muthukumaran et al. 1997). Although IFN-γR1 alone cannot initiate signal transduction, both the chimeric EpoR/γR1 (extracellular/intracellular) homodimer and the EpoR/γR1–EpoR/γR2 heterodimer generate responses characteristic of IFN-γ in response to Epo. Thus, the configuration of the extracellular domains influences the architecture of the intracellular domains.

In contrast to the growth hormone (GH) receptor (de Vos et al. 1992) and the EpoR (Watowich et al. 1992)

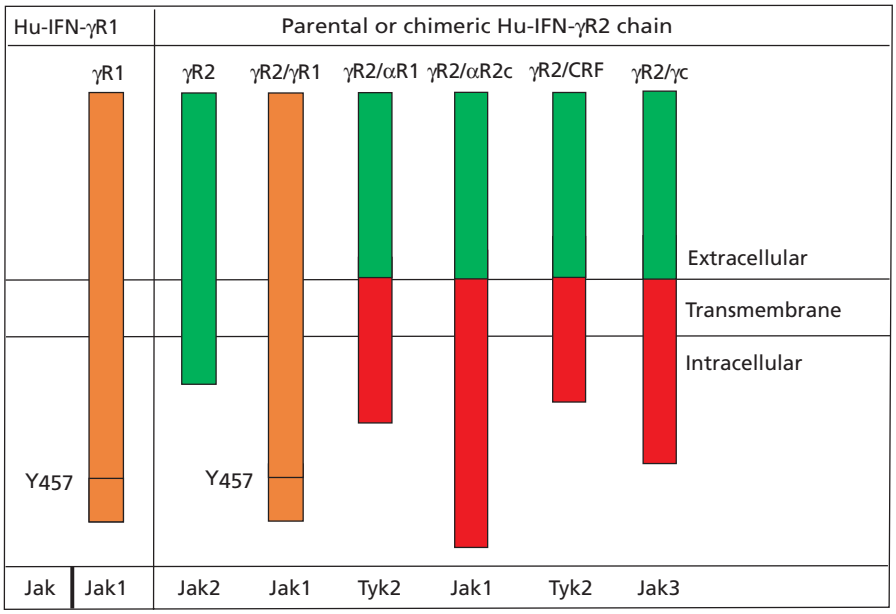

Figure 9 *Structure of chimeric receptors. Hu-IFN-γR1 (γR1) and Hu-IFN-γR2 (γR2) are the intact chains of the human IFN-γ receptor complex. All chimeric receptors have the extracellular domain of the human IFN-γR2 and the transmembrane and intracellular domains of different human receptors: γR2/γR1, Hu-IFN-γR1; γR2/αR1, Hu-IFN-αR1 (Uzé et al. 1990); γR2/αR2, Hu-IFN-αR2c (Domanski et al. 1995; Lutfalla et al. 1995); γR2/CRF, CRFB4 (Lutfalla et al. 1993); γR2/γC, IL-2 receptor γ_C chain (Takeshita et al. 1992). The short form Hu-IFN-αR2b binds Jak1 (Novick et al. 1994), but does not support signal transduction.*

complexes, when one IFN-γ homodimer binds two IFN-γR1 molecules, the two receptor subunits do not interact with one another and are separated by 2.7 nm (Walter et al. 1995) at their closest point. Therefore, although the IFN-γR1 chain possesses both a Jak1-association site and a Stat1α-recruitment site, alone it is unable to transduce a signal on homodimerization because the two Jak1 kinases are not in physical proximity to permit transphosphorylation (Figure 10a). Crystallographic analysis of the IFN-γ–IFN-γR1 complex suggests that each monomer of the IFN-γ homodimer binds one IFN-γR1 and one IFN-γR2 subunit (Walter et al. 1995). Thus the signal-transducing complex of IFN-γ consists of the IFN-γ homodimer bound to two IFN-γR1 and two IFN-γR2 chains (see Figures 8 and 10b) which recruit Jak1 and Jak2, respectively (Kotenko et al. 1995, 1996; Muthukumaran et al. 1996, 1997) and Jak2 phosphorylates Jak1, after which either kinase phosphorylates Tyr-457 of the IFN-γR1 chain. The phosphorylated segment of each IFN-γR1 chain recruits Stat1α, which is then phosphorylated by Jak1 or Jak2, and released to dimerize and form the active Stat1α. In contrast, with the EpoR/γR1 dimer, two Jak1 kinases are brought sufficiently close together to activate one another (Figure 10c). In the case of the EpoR/γR1–EpoR/γR2 dimer, one Jak1 and one Jak2 are in close apposition for Jak2 to phosphorylate Jak1 and initiate efficient downstream signaling events (Figure 10d). A major function of receptor dimerization is to bring two receptor-associated kinases together for transactivation and phosphorylation of the receptor chains. The cytoplasmic domain of the IFN-γR2 subunit serves to bring Jak2 kinase into the signal transduction complex (see Figures 8 and 10b) because the IFN-γR1 chain alone cannot bring Jak1 into sufficient proximity to initiate signal transduction.

For hormones, growth factors, and cytokines, the conversion of the extracellular ligand-binding event to the intracellular signal involves a change in the structure of the receptor. Depending on the ligand, this can take the form of receptor homodimers (Epo, GH), heterodimers (ciliary neurotropic factor (CNTF), leukemia inhibitory factor (LIF)), homotrimers (tumor necrosis factor (TNF)), and more complex assemblies (Stahl and Yancopoulos 1993). The IFN-γR2 subunit is a helper receptor subunit with a Jak2-association site, but no Stat-recruitment site; its intracellular domain can be substituted with the cytoplasmic domain of any receptor subunit that can bring a Jak kinase to the IFN-γ receptor complex to support signal transduction (Kotenko et al. 1996; Muthukumaran et al. 1996).

We propose that the multichain cytokine class II receptors have two major chains exemplified by the IFN-γ receptor complex (see Figure 10b). The ligand-binding chain (IFN-γR1) and the accessory chain (AC) (IFN-γR2; helper receptor) serve as a foundation for the functional IFN-γR complex (Kotenko et al. 1995, 1996; Muthukumaran et al. 1996, 1997). The geometry of the IFN-γR1 chain is such that its homodimerization yields a nonfunctional intracellular receptor complex. The accessory chain completes this function (see Figure 10b). The question arises of why

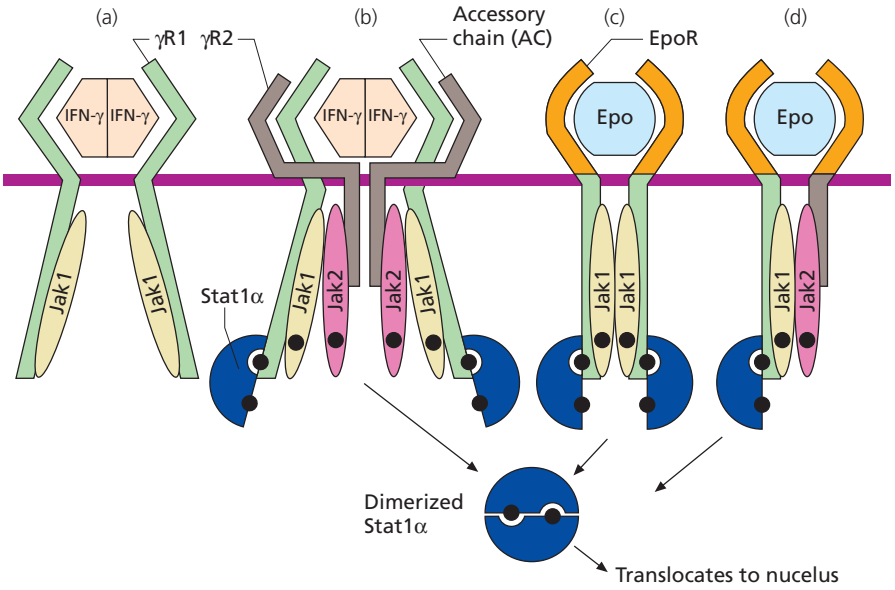

Figure 10 *Schematic representation of receptor complexes.* **(a)** *The IFN-γR1 homodimer bound to IFN-γ. The cytoplasmic domains of the two chains are too far apart to permit transactivation of the two Jak1 kinases.* **(b)** *The active heteromeric IFN-γ receptor complex with two IFN-γR1 and two IFN-γR2 subunits per complex. The IFN-γ homodimer binds to two IFN-γR1 chains, followed by its interaction with two IFN-γR2 chains. The associated Jak2 and Jak1 kinases activate one another by transphosphorylation, with subsequent phosphorylation and dimerization of Stat1α.* **(c)** *The EpoR/IFN-γR1 homodimer which, unlike the IFN-γR1 homodimer, permits transactivation of the two Jak1 molecules.* **(d)** *The structure of the heterodimer of EpoR/IFN-γR1 and EpoR/IFN-γR2 which is the putative active receptor complex.*

two separate chains should have evolved when one in the correct configuration would suffice. We postulate that the presence of two distinct chains provides more effective control and fine-tuning of responses to ligand, e.g. the differences in response of T-helper (Th)1 and Th2 cells to IFN-γ results from the lack of expression of the IFN-γR2 chain in the Th1 subset (Adolf et al. 1990, 1991) and allows exquisite fine-tuning of sensitivity to IFN-γ. It is also possible that receptors with multiple chains could recruit additional factors into the complex to generate a wider variety of intracellular signals. This could explain how receptors with multiple subunits could activate a greater number of specific pathways and signals than those with fewer elements in the receptor complex.

THE TYPE I INTERFERON (IFN-α/β/ω) RECEPTOR

Chromosomal localization, antibodies, and cDNA clones

Somatic cell genetic studies with human–rodent hybrid cells containing various combinations of human chromosomes have provided evidence that the presence of human chromosome 21 confers sensitivity of the rodent cells to human type I interferons (Tan et al. 1973; Slate et al. 1978; Epstein et al. 1982; Raziuddin and Gupta 1985). It was also demonstrated that antibodies to human chromosome 21-encoded cell surface components were able to block the action or binding of Hu-IFN-α to cells (Revel et al. 1976; Shulman et al. 1984). Later, Langer et al. (1990) demonstrated that 3x1S irradiation-reduced hamster–human somatic hybrid cells containing about 3 Mb (megabases) of chromosome 21q around 21q22.1 (Jung 1991; Soh et al. 1994c) were able to bind ^{32}P-labeled Hu-IFN-αA and generate a complex of about 150 kDa when crosslinked to the cell surface. During this time, the gene for the Hu-IFN-αR1 receptor chain was mapped to the 3x1S region (21q22.1) (Lutfalla et al. 1990). The paradoxical observation that Chinese hamster ovary 3x1S cells could bind Hu-IFN-αA, whereas the expression of the cloned receptor cDNA (Hu-IFN-αR1) in mouse cells did not confer binding to Hu-IFN-αA, suggested that the 3x1S region of human chromosome 21 contains other subunits of the receptor complex. This assumption was supported by the identification of two separate components after immunoprecipitation of ^{125}I-labeled Hu-IFN-αA–receptor complexes from 3x1S cell extracts with anti-IFN-α receptor antibody (Colamonici et al. 1990, 1992; Colamonici and Domanski 1993). These two subunits differ from the cloned Hu-IFN-αR1. The monoclonal antibodies (MAbs) against one subunit (110 kDa) and the recombinant Hu-IFN-αR1 receptor locked the biological activity of type I interferons whereas MAbs against the second subunit did not (Colamonici et al. 1990, 1992; Benoit et al. 1993; Colamonici and Domanski 1993), suggesting that the type I IFN receptor consists of at least two

different subunits. Antibodies to Hu-IFN-αR1 blocked the activity of various type I interferons (Uzé et al. 1991). Thus, it was likely that the Hu-IFN-αR1 molecule was at least one component of the type I IFN receptor.

Mouse cells with functional Hu-IFN type I IFN receptors were first isolated by Jung and Pestka (1986) and Revel et al. (1991). The mouse cells transfected with total human DNA exhibited the properties of a type I interferon receptor (also designated Hu-IFN-αR, Hu-IFN-βR, or Hu-IFN-α/βR) in that they responded to two type I interferons tested: Hu-IFN-α and Hu-IFN-β. Although primary transformants were obtained by these groups, no molecular clone was obtained that provided type I interferon receptor activity. Employing the procedures of Jung and Pestka (1986); Uzé et al. (1990), by switching the selection procedure from Hu-IFN-αA and Hu-IFN-β to Hu-IFN-αB2 (a more species-specific Hu-IFN-α), were able to obtain a molecular clone which they designated the type I IFN receptor. However, as shown by them and other groups, this cDNA clone, when expressed in mouse or hamster cells, did not bind all type I interferons other than Hu-IFN-αB2 and yielded very little response even to Hu-IFN-αB2. However, Hu-IFN-αR1 expressed in xenopus oocytes to minimize the possibility of endogenous receptor components can bind and be covalently crosslinked to Hu-IFN-αA and Hu-IFN-αB, although to a small degree (Lim et al. 1994). None of the other Hu-IFN-α species tested seemed to activate the mouse cells expressing this cDNA clone. During this period, however, a number of groups obtained antibodies, suggesting that the type I receptor consisted of multiple components, a hypothesis consistent with the inability of Jung and Pestka (1986) to obtain stable secondary transformants. A comparison of hamster cells with the 3x1S region of human chromosome 21 and cells transfected with the Hu-IFN-αR1 cDNA showed that other components were involved in the type I interferon receptor. Hamster cells with the 3x1S region of human DNA responded to Hu-IFN-αA and Hu-IFN-β, whereas mouse or hamster cells with the Hu-IFN-αR1 cDNA did not respond to low concentrations of these interferons (Langer et al. 1990; Soh et al. 1994c).

As noted above, cloning of the first human type I IFN receptor chain (IFN-αR1) was reported on the basis of rendering mouse cells sensitive to Hu-IFN-αB2 (Uzé et al. 1990). However, when mouse cells were transfected with the Hu-IFN-αR1 cDNA, they did not exhibit binding and antiviral protection with type I IFN subtypes other than Hu-IFN-αB2. Similarly, human cells transfected with the homologous cloned mouse Mu-IFN-αR1 receptor cDNA showed antiviral protection activity with only Mu-IFN-α11. However, the expression of this Mu-IFN-αR1 cDNA in murine L1210 R101 cells resistant to type I IFNs and lacking mRNA for this Mu-IFN-αR1 receptor component showed antiviral protection in response to all type I Mu-IFNs tested (Uzé et al. 1992). In contrast, it was reported that, when CHO-K1 cells were transfected with the cloned Hu-IFN-αR1 cDNA, no induction of 2′,5′-oligoadenylic acid synthetase activity was observed after treating cells with Hu-IFN-αA and Hu-IFN-αB2 (Revel et al. 1991).

In affinity, crosslinking experiments, ^{125}I-labeled Hu-IFN-α–receptor complexes with an M_r of 80 000 (Hannigan et al. 1986), 210 000 (Colamonici et al. 1992), 260 000 (Vanden Broecke and Pfeffer 1988), or 300 000 (Raziuddin and Gupta 1985) were observed, in addition to the major complex that migrates as a broad band with an M_r of 140 000–150 000. These observations strongly suggested that other subunits, components or accessory proteins, are involved in ligand binding and in signal transduction in response to type I IFNs (Colamonici and Pfeffer 1991; Mariano et al. 1992; Abramovich et al. 1994b) as described for the IFN-γ receptor (Jung et al. 1987; Cook et al. 1992, 1994; Soh et al. 1993, 1994a).

Functional YAC selection and screening

Jung et al. (1987, 1988, 1990; Jung 1991) attempted to obtain the gene and/or cDNA clone for Hu-IFN-γR2 in studies that served as a foundation for isolation of a genomic clone encoding the functional type I IFN receptor complex. However, the use of cDNA expression libraries, cosmid genomic clones, and total human DNA proved inadequate to obtain a molecular clone for Hu-IFN-γR2. We thus turned to the use of yeast artificial chromosomes (YAC) because they contain large inserts of human DNA. YAC cloning techniques allow the cloning of DNA fragments from 100 to 2000 kb. (Burke et al. 1987; Chumakov et al. 1992a). The large insert size not only facilitates physical mapping (Chumakov et al. 1992b), but also makes it possible to express genes that are larger than permitted by conventional cloning procedures and regions of chromosomes containing multiple genes. To use YACs for fusion to mammalian cells and selection, it was necessary to devise and construct plasmids that would insert mammalian markers into the YACs so that the appropriate cells could be selected (Soh et al. 1994b; Emanuel et al. 1995). In addition, we designed vectors that would fragment the YAC clones into more manageable smaller ones (Cook et al. 1993, 1994; Emanuel et al. 1995). By examining a number of YACs containing human DNA inserts from this region, we were able to find one that contained the gene for the Hu-IFN-γR2 chain. Having successfully used this approach to obtain a functional Hu-IFN-γ receptor, we then applied this YAC technology to examine the type I interferon system.

A functional human interferon type I receptor

With the knowledge that the 3x1S region of human chromosome 21 contained the genes for the type I inter-

feron receptor, we screened three YAC clones from this region. Two YACs were initially screened by a primer pair derived from the 524-5P probe (*21S58* locus) near the cloned Hu-IFN-αR1 receptor gene (Lutfalla et al. 1992). Tassone et al. (1990) reported that the two loci (*21S58* and *IFNAR*) were located within 170 kb of each other. It was also reported that the *CRFB4* gene identified by the 524-5P probe was located at less than 35 kb from the Hu-IFN-αR1 gene (Lutfalla et al. 1993). The αYAC containing the gene for the cloned Hu-IFN-αR1 receptor cDNA was selected for expression into hamster cells based on the assumption that all the genes involved in forming a functional type I IFN receptor might be encompassed on this YAC. The objective was to obtain a YAC clone that would support type I human interferon activity when transferred into hamster cells. We found one YAC clone that fit our criteria. It contained the genes for the cloned Hu-IFN-αR1 receptor subunit and other genes in the 3x1S region of chromosome 21. In addition, the introduction of this YAC clone, designated αYAC, into hamster cells rendered the cells much more sensitive to Hu-IFN-αA and Hu-IFN-αB2, and somewhat more sensitive to Hu-IFN-ω and Hu-IFN-β (Soh et al. 1994c). We thus hypothesized that this YAC clone must contain multiple genes required to reconstitute a fully functional type I IFN receptor.

Antiviral protection of hamster cells containing the Hu-IFN-αR1 cDNA or the αYAC

The hamster cells fused to spheroplasts with the αYAC containing the type I interferon receptor complex showed increased sensitivity to Hu-IFN-αA and Hu-IFN-αB2 in antiviral protection against EMCV and vesicular stomatitis virus (VSV) when compared with the parental hamster 16-9 cells or hamster cells transfected with the Hu-IFN-αR1 receptor cDNA (Soh et al. 1994c). The hamster cells containing the αYAC exhibited large increases in sensitivity to Hu-IFN-αA and Hu-IFN-αB2. Furthermore, there was substantial increase in sensitivity to Hu-IFN-β and Hu-IFN-ω. When the sensitivity of the cells to the interferons was evaluated, in all cases hamster cells with the αYAC showed substantial increase in sensitivity to all type I interferons ranging from about threefold to more than 100-fold. There was little or no increased sensitivity of the comparable cells containing the cloned Hu-IFN-αR1 cDNA.

Induction of class I MHC surface antigens

Subclones isolated from transformed hamster 16-9 cells, which express the human HLA-B7 antigen, fused to the αYAC or transfected with the Hu-IFN-αR1 cDNA exhibited HLA-B7 induction as a function of IFN concentration for all of the type I IFNs tested. Hu-IFN-αA, Hu-IFN-αB2, Hu-IFN-β, and Hu-IFN-ω had little or no effect on the parental hamster 16-9 cells or hamster 16-9 cells transfected with the Hu-IFN-αR1 cDNA. However, hamster cells fused to the αYAC showed enhanced levels of HLA-B7 antigens in response to Hu-IFN-αA, Hu-IFN-αB2, Hu-IFN-β, and Hu-IFN-ω. Treatment of hamster cells fused with the αYAC with as little as 1 unit/ml of Hu-IFN-αA, Hu-IFN-αB2, Hu-IFN-ω, or Hu-IFN-β gave a significant HLA-B7 induction whereas parental hamster 16-9 cells or 16-9 cells transfected with the Hu-IFN-αR1 cDNA did not show any significant induction at this level (Soh et al. 1994c).

Cells containing the αYAC can bind ^{32}P-labeled Hu-IFN-αA and ^{32}P-labeled Hu-IFN-αB2

The hamster cells with the αYAC bound ^{32}P-labeled Hu-IFN-αA-P1 and ^{32}P-labeled Hu-IFN-αB2-P quite well. There was a small level of binding of ^{32}P-labeled Hu-IFN-αB2-P to cells containing the Hu-IFN-αR1 cDNA, but no binding of ^{32}P-labeled Hu-IFN-αA-P1 was seen. Furthermore, competition binding studies with ^{32}P-labeled Hu-IFN-αA-P1 as the labeled ligand showed that Hu-IFN-αA, Hu-IFN-αB2, Hu-IFN-β, and Hu-IFN-ω all compete effectively for ^{32}P-labeled Hu-IFN-αA-P1 binding to hamster cells with the αYAC as well as to human Daudi lymphoblastoid cells (Soh et al. 1994c). The specific binding of Hu-IFN-αA and Hu-IFN-αB2 to cells containing the αYAC and the competition by all type I interferon classes together with the activity data indicate that the human DNA insert in this YAC contains the genes encoding the subunits that comprise a functional type I receptor. As the Hu-IFN-αR1 gene is included in this DNA insert, one or more additional genes complementing the cloned Hu-IFN-αR1 receptor encoded on this YAC enable the cells to bind these interferons effectively (Soh et al. 1994c).

Proof that the IFN-αR1 component is part of the type I receptor complex

A large number of experiments were consistent with the concept that the IFN-αR1 chain was one component of the type I receptor complex. IFN-α-resistant K562 cells can bind type I IFNs, but are restored to IFN-α sensitivity by the introduction of Hu-IFN-αR1, without any apparent change in receptor number or affinity, suggesting a role for Hu-IFN-αR1 in cellular signaling (Colamonici et al. 1994a). Evidence for the role of IFN-αR1 in signal transduction includes the enhanced sensitivity to IFNs seen in some transfection studies, sometimes in the absence of enhanced IFN binding (Colamonici et al. 1994a; Constantinescu et al. 1994) and the interaction of IFN-αR1 with the intracellular tyrosine kinase Tyk2,

required for IFN-α responses (Velazquez et al. 1992; Barbieri et al. 1994; Colamonici et al. 1994b).

Direct proof of the requirement for the IFN-αR1 chain for type I interferon receptor function was demonstrated by experiments disrupting the IFN-αR1 gene. Homozygous deletions of *IFNAR1* in mice (IFN-αR$^{0/0}$) were reported to cause enhanced susceptibility to several viruses and eliminate antiproliferative activity of IFN-α and IFN-β (Müller et al. 1994; Hwang et al. 1995). Primary embryo fibroblasts from such mice lack type I IFN-stimulated resistance to viruses and inducibility of 2′,5′-oligoadenylic acid synthetase. Using homologous recombination targeted to the αYAC, Cleary et al. (1994) produced a deletion within the human IFN-α receptor (Hu-IFN-αR1) gene which eliminated exon II of the gene. The resultant αYAC was transferred to CHO cells. This deletion effectively eliminated the ability of type I interferons to induce MHC Class I antigens and exhibit antiviral activity, which are properties of the fully functional parental YAC clone (Soh et al. 1994c). By subsequent transfection of the cDNA for Hu-IFN-αR1 into cells containing the αYAC, antiviral activity and ability of Hu-IFN-α to stimulate MHC class I antigens was successfully reconstituted. The Hu-IFN-αR1 subunit thus plays a critical role in the functional human type I IFN receptor complex, the components of which are encoded on this YAC. In addition, as binding of ligands is retained in the cells containing the YAC with the deletion, it was clear that one or more additional subunits encoded on the YAC are responsible for ligand binding and activity.

Proof that the IFN-αR2c chain is required for function of the type I interferon receptor

After our studies describing the αYAC, a second chain, IFN-αR2b, which was suggested as another component of the type I interferon receptor complex, was reported, but it appeared to exhibit no intrinsic activity alone or together with the Hu-IFN-αR1 chain (Novick et al. 1994). The human gene *IFNAR2* encoding this chain is located on the αYAC and also localizes to the 3x1S region of chromosome 21. This Hu-IFN-αR2b chain was reported to bind type I interferons and antibodies to this chain were able to co-immunoprecipitate Jak1 (Novick et al. 1994). However, expression of IFN-αR1 or IFN-αR2b chains, or the combination of both, in hamster cells was not able to reconstitute functional human receptor activity (Mariano et al. 1994; Soh et al. 1994b; Kotenko et al. 1995). In addition, the CHO cells containing the ΔαYAC with the disrupted *IFNAR1* gene retained the ability to bind Hu-IFN-αA and Hu-IFN-αB2 (Cleary et al. 1994). This paradox was partially resolved when U5 cells (Darnell et al. 1994) that do not respond to type I interferons were able to be reconstituted to respond to the interferons by introduction of the αYAC (J. Cook, S. Pestka, I. Kerr, and G. Stark, unpublished data). Unfortunately, no stable transformants were obtained with the αYAC in U5 cells. The data indicated, however, that another component encoded on the αYAC was necessary for response to type I interferons. This component was subsequently cloned (Domanski et al. 1995; Lutfalla et al. 1995) and shown to be a long form of the Hu-IFN-αR2b chain called Hu-IFN-αR2c (see Table 7). All three chains (Hu-IFN-αR2a, -αR2b, and -αR2c) are encoded by the same *IFNAR2* gene. The Hu-IFN-αR2c gene contains a large intracellular domain compared with the short domain of the Hu-IFN-αR2c chain. The Hu-IFN-αR2c chain reconstitutes U5 cells for responses to type I interferons. The Hu-IFN-αR2a protein is a soluble form of the receptor consisting of the extracellular domain of the Hu-IFN-αR2b and Hu-IFN-αR2c chains.

Hamster cells containing the αYAC exhibit the properties expected for a functional type I human IFN receptor complex. The YAC provides genes which are necessary and sufficient to encode this functional type I interferon receptor complex as measured by three distinct biological assays and by binding of both ^{32}P-labeled Hu-IFN-αA and ^{32}P-labeled Hu-IFN-αB2 to cells fused to this αYAC.

Diversity of the interaction of type I interferons with the receptor

As noted above CHO cells containing the YAC F136C5 (αYAC) respond to all type I human interferons including IFN-αA, IFN-β, and IFN-ω. The αYAC contains at least two genes encoding IFN-αR chains that are required for response to type I human interferons: Hu-IFN-αR1 and Hu-IFN-αR2c. We previously isolated a splice variant of the Hu-IFN-αR1 chain designated Hu-IFN-αR1s or Hu-IFN-αR1b (Cleary et al. 1992) (see Table 7). CHO cells containing the disrupted αYAC, which contains a deletion in the Hu-IFN-αR1 gene, ΔαYAC, were transfected with expression vectors for the Hu-IFN-αR1 and Hu-IFN-αR1s chains. With these cells, two type I interferons were identified that can interact with the splice variant (Hu-IFN-αR1s) and with the Hu-IFN-αR1 chains: Hu-IFN-αA and Hu-IFN-ω. Two other type I interferons – Hu-IFN-αB2 and Hu-IFN-αF – are capable of signaling through the Hu-IFN-αR1 chain only, and cannot utilize the splice variant Hu-IFN-αR1s. Hu-IFN-αR1 and Hu-IFN-αR1s differ in that the latter is missing a single subdomain of the four subdomains of the receptor extracellular domain encoded by exons 4 and 5 of the Hu-IFN-αR1 gene. Therefore, different type I interferons require different subdomains of the Hu-IFN-αR1 receptor chain.

These results with the various forms of the Hu-IFN-α receptor components generally demonstrate differences

in interaction of all the type I interferons with the receptor that reflect the differences in the activity profiles of the interferons. Specifically, some type I interferons (e.g. Hu-IFN-B2, Hu-IFN-αF) require the two subdomains absent in the splice variant (Figure 11) and some can function without these domains (e.g. Hu-IFN-αA, Hu-IFN-ω) as described by Cook et al. (1996). The results indicate that the various Hu-IFN-α species and other type I interferons interact with the receptor differently, thereby accounting for their differential activities. The conservation of the multitude of type I interferons throughout evolution of the mammals is consistent with unique functional roles for each of the type I interferons.

THE CYTOKINE TYPE 2 RECEPTOR FAMILY

The IFN-αR1, IFN-αR2, CRFB4, IFN-γR1, and IFN-γR2 chains are members of the cytokine type 2 receptor family as described by Bazan (1990a, b) and by Thoreau et al. (1991), who proposed that the interferon receptors as well as other receptors for cytokines and some growth factors are composed of two folding domains that comprise the ligand-binding site, which resides in the crevice between the folds. The primary cytokine–receptor interaction was suggested to involve one face of the ligand whereas another face of the bound cytokine can interact with accessory binding components. A summary of these receptors for the interferon-related receptor components is illustrated in a recent review (Kotenko and Pestka 2000). These homologies relate the interferon receptor components to the fibronectin type III structure, which in turn relates all these structures to the immunoglobulin superfamily.

SIGNAL TRANSDUCTION

All type I IFNs activate Jak1 and Tyk2 tyrosine kinases during signal transduction, leading to formation and activation of ISGF3 (IFN-α-stimulated gene factor 3), DNA-binding complexes consisting of Stat1 and Stat2 transcriptional factors and p48 DNA-binding protein from the IFN regulatory factor (IRF) family of proteins (Fu et al. 1990, 1992; Schindler et al. 1992; Veals et al. 1992; Müller et al. 1993). Two subunits of the type I IFN receptor complex were identified: Hu-IFN-αR1 and Hu-IFN-αR2c and its variants as described above (Novick et al. 1994; Domanski et al. 1995; Lutfalla et al. 1995).

Some Stats are activated by a number of cytokines; others are highly specific. Stat2 has been shown to be activated only in response to type I IFN (Fu et al. 1992). A number of studies were made to define how Stat1 and Stat2 are recruited to the type I IFN receptor complex (Uddin et al. 1995; Domanski and Colamonici 1996; Yan et al. 1996; Li et al. 1997). Although it is clear that both receptors are necessary for signaling of type I IFNs, because disruption of any one of them completely abolishes the ability of cells to respond to type I IFNs (Hwang et al. 1995; Lutfalla et al. 1995), the reports about their role in Stat recruitment were inconclusive. The IFN-αR1 chain as well as both forms of the IFN-αR2 chain, the IFN-αR2c and the IFN-αR2b chain, were reported to associate with Stat proteins (Uddin et al. 1995; Domanski and Colamonici 1996; Krishnan et al. 1996; Yan et al. 1996; Yang et al. 1996).

The difficulty in evaluating the contribution of each chain of the IFN-α receptor complex to signal transduction is the result of the lack of cell lines without the endogenous receptor chains and in the cross-species activity of the type I IFNs. To overcome these limita-

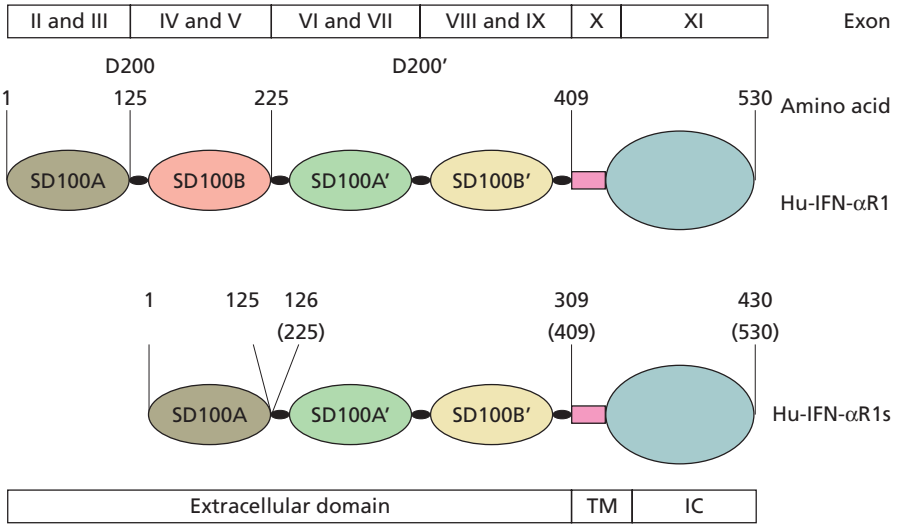

Figure 11 *Schematic Illustration of the Hu-IFN-αR1 chain and the splice variant Hu-IFN-αR1s. The domains of the Hu-IFN-αR1 chain are shown. The splice variant chain, Hu-IFN-αR1s, lacks exons 4 and 5.*

tions we used chimeric receptors with the extracellular human IFN-γ receptor chains expressed in hamster cells because Hu-IFN-γ is highly species specific and does not activate the endogenous hamster IFN-γ receptor. This strategy with the use of chimeric receptors (Kotenko et al. 1999) permitted us to show that the IFN-αR2c chain alone is necessary and sufficient for recruitment of Stat1 and Stat2.

Results of other workers have implicated all the receptor subunits of the IFN-α receptor complex (the IFN-αR1, IFN-αR2b, and IFN-αR2c chains) in Stat activation (Uddin et al. 1995; Domanski and Colamonici 1996; Yan et al. 1996; Li et al. 1997). The IFN-αR1 chain was reported to bind Stat2 and Stat3 in a ligand-dependent manner through the phosphorylated Tyr466 and the phosphorylated Tyr527, respectively (Yan et al. 1996; Yang et al. 1996; Li et al. 1997). It was originally demonstrated that the peptide containing phosphorylated Tyr466 (P-Tyr466) can inhibit type I IFN signaling in permeabilized cells and specifically interact with the -SH_2 domain of Stat2, but not of Stat1 (Yan et al. 1996). Later the P-Tyr466 peptide, which was one amino acid longer, was shown to interact with both Stat1 and Stat2 proteins (Li et al. 1997). However, mutation of all four tyrosine residues within the IFN-αR1 intracellular domain to phenylalanine resulted in a functional receptor (Gibbs et al. 1996), demonstrating that phosphorylation of the IFN-αR1 chain is unnecessary for the generation of a biological response. The IFN-αR2c chain was shown to bind both Stat1 and Stat2 in a ligand-independent manner (Domanski and Colamonici 1996; Li et al. 1997). As Stat1 activation by type I IFNs is Stat2 dependent (Improta et al. 1994; Leung et al. 1995), it was proposed that Stat1 is recruited to the complex through Stat2 (Leung et al. 1995; Li et al. 1997). The short form, the IFN-α2b chain, was reported to associate with Stat2 in a ligand-dependent manner (Uddin et al. 1995). However, most experiments were performed in cells where the endogenous type I receptor subunits were present. It is thus likely that endogenous components interacting with the heterologous type I interferon components in the host cells contributed to the results previously reported.

In our experiments with chimeric receptors, we could isolate the contributions of endogenous and exogenous components which was not possible previously (Kotenko et al. 1999). The chimeric receptors with the IFN-γR2 extracellular domain and intracellular αR1 and αR2c intracellular domains were expressed in hamster cells expressing the Hu-IFN-γR1 chain. The γR2/αR1 and γR2/αR2c chimeras rendered 16-9 cells sensitive to Hu-IFN-γ as measured by IFN-γ-induced MHC class I antigen expression and Stat1α activation as did the intact γR2/γR2. The γR2/αR2b was unable to support IFN-γ signaling because the IFN-αR2b intracellular domain does not associate with any kinase as we demonstrated previously (Fu 1995). The IFN-γ-induced activation of Stat1α DNA-binding complexes in hamster cells expressing chimeric receptors correlated with MHC class I antigen induction; however, formation of the IFN-γ-induced ISGF3 DNA-binding complexes was detected only in γR2/αR2c cells (Kotenko et al. 1999). Thus, we demonstrated that the Stat2 protein can be recruited and activated in cells expressing the chimeric receptor complex where the γR2/γR2 chain is substituted by the γR2/αR2c chimeric chain, but not by the γR2/αR1 or the γR2/αR2b chimeric chains, demonstrating that recruitment and activation of Stat2 occur through the intracellular domain of the IFN-αR2c chain. In addition, the γR2/αR2c chimeric chain expressed in these cells was able to support IFN-γ-induced antiviral protection against EMCV.

In the γR2/αR2c cells the presence of the Hu-IFN-γR1 chain, which recruits Stat1α to the receptor complex, did not allow us to answer the question of whether or not the presence of the IFN-αR2c intracellular domain is sufficient only for recruitment, and activation of Stat1α and Stat2 for formation of the ISGF3 DNA-binding complexes and the resultant biological activities. To define the requirements for Stat2 recruitment further, we switched to a hamster cell line expressing the Hu-IFN-γR2 chain which does not recruit any Stats, unlike the IFN-γR1 chain. Thus, the chimeric receptors with the IFN-γR1 extracellular domain expressed in these cells were the only chains that could contribute to Stat recruitment. Therefore, MHC class I antigen induction in these cells could serve as a marker of Stat activation. The cells expressing the γR1/γR1 and γR1/αR2c chimeras demonstrated IFN-γ-induced MHC class I antigen expression, whereas the γR1/γR1 and γR1/αR2b cells did not (Kotenko et al. 1999). Similarly, Stat1α DNA-binding complexes and small amounts of Stat3 DNA-binding complexes were activated in the γR1/γR1 and γR1/αR2c cells, but not in the γR1/γR1 and γR1/αR2b cells (Kotenko et al. 1999). However, ISGF3 DNA-binding complexes were induced only in γR1/αR2c cells (Kotenko et al. 1999). Thus, the presence of the IFN-αR2c intracellular domain as the only Stat-recruiting domain in the chimeric receptor complex is sufficient for Stat1, Stat2, and Stat3 recruitment, ISGF3 DNA-binding complex activation, and induction of MHC class I antigens. Only when the IFN-αR2c intracellular domain was present in the chimeric receptor was IFN-γ able to induce antiviral protection in cells.

We therefore conclude that all Stats activated by type I IFNs, Stat1, Stat2, and Stat3 are activated through the IFN-αR2c intracellular domain (Figure 12). The IFN-αR1 intracellular domain does not recruit Stats, but supports type I IFN signal transduction by bringing Tyk2 tyrosine kinase to the receptor complex and modulates type I IFN signaling. Stat recruitment by the type I IFN receptor complex is solely a function of the IFN-αR2c intracellular domain and the IFN-αR2c chain is sufficient and necessary for recruitment of Stat1, Stat2, and Stat3.

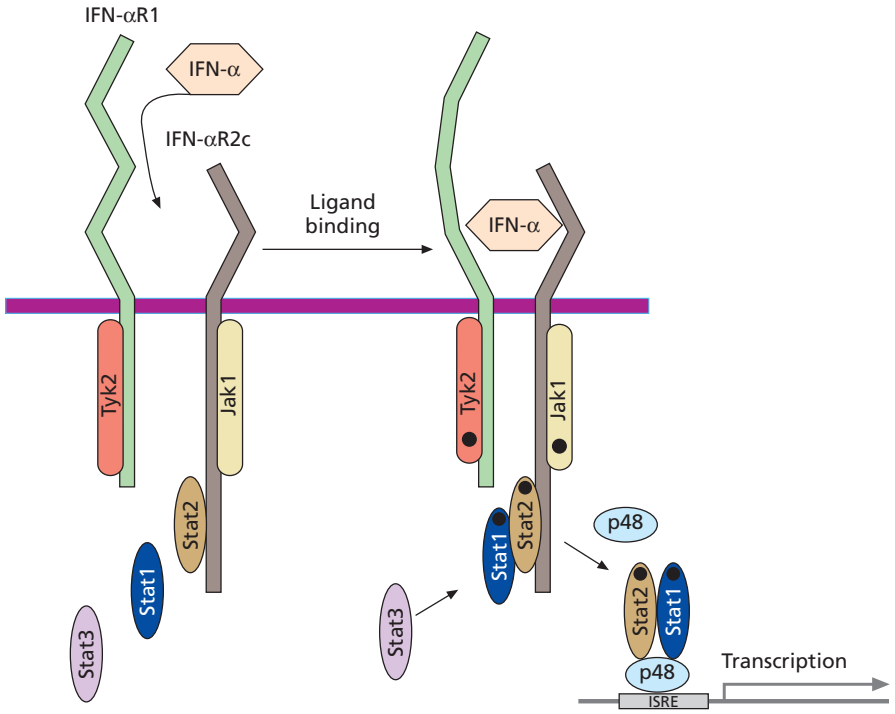

Figure 12 *Model of type I interferon (IFN)–receptor complex and signaling. Ligand binding to the subunits of the type I IFN receptor complex, the IFN-αR2c and the IFN-αR1 chains, initiates the cascade of signal transduction events. All Stats involved in IFN-α signaling are activated through the intracellular domain of the IFN-αR2c chain.*

Receptor and signal transduction endnote

Although two major components of the type I interferon receptor have been identified, a number of results suggest that there are other components yet to be delineated (Abramovich et al. 1994a; Cook et al. 1996; Hertzog et al. 1994). The crystal structures of Mu-IFN-β (Mitsui et al. 1993; Senda et al. 1995) and Hu-IFN-α2b (Radhakrishnan et al. 1996) and solution structure (Klaus et al. 1997) provide a foundation to develop an understanding of the interferon–receptor interactions further. The beginning of the elucidation of the type I interferon receptor is just starting with undoubtedly many surprises to come.

THERAPEUTIC USE OF TYPE I INTERFERONS

Interferons have been used in clinical trials for about three decades, but were not approved by regulatory agencies until the 1980s. The recombinant human interferons (IFN-α, IFN-β, and IFN-ω) and bovine IFN-τ have been used in clinical trials since 1981. Hu-IFN-αA (Hu-IFN-α2a) was the first recombinant interferon approved for clinical trial; and both Hu-IFN-αA (Hu-IFN-α2a) and Hu-IFN-α2 (Hu-IFN-α2b) were approved by regulatory agencies in many countries about the same time in the mid-1980s. The first approvals were for hairy cell leukemia and Kaposi's sarcoma. Since that time, they have been found to be useful in a variety of cancers and viral diseases. The Hu-IFN-αs have been approved for the treatment of a broad range of cancers such as CML (Talpaz et al. 1987; Faderl et al. 2000) and metastatic malignant melanoma (Sun and Schuchter 2001; Gray et al. 2002; Kilbridge et al. 2002; Kirkwood 2002; Kirkwood et al. 2002). They have been used in many clinical protocols for the treatment of other cancers with significant effects. In some cancers a small subset of patients seems to respond, but the genotype or phenotype of the responders has not been identified. It would be a major advance if the responders could be identified by genomic or other markers, a goal that many investigators are pursuing. Clinical trials continue in many cancers such as renal cell cancer (Hofmockel et al. 1997; Dutcher et al. 2001; van Herpen and De Mulder 2002) and many others (Cooper 1991; Einhorn and Strander 1993; Portillo Martin et al. 1995; Pfeffer et al. 1998; Ravandi et al. 1999; Borden et al. 2000; Oberg 2000; Eliason 2001; Jonasch and Haluska 2001; Brassard et al. 2002; Nathan and Eisen 2002). A summary of the approved therapeutic indications for interferons is given in Table 9. Local regional therapy has been attempted (van Herpen and De Mulder 2000), but effective delivery or sustained-release systems have not yet been developed.

Although interferons were first discovered because of their antiviral activity, they have not yet been used

Table 9 *Therapeutic activities of interferons*

Approved therapeutic interventions	
Hairy cell leukemia[a]	Kaposi's sarcoma[a]
Renal cell leukemia[a]	Non-Hodgkin's lymphoma[a]
T-cell lymphoma[a]	Multiple myeloma[a]
Laryngeal papillomatosis[a]	Malignant melanoma[a]
Bladder cell carcinoma[a]	Colon carcinoma[a]
Condyloma scuminatum[a]	Rhinovirus (prevention)[d]
Chronic hepatitis B[a]	Chronic hepatitis C (NANB)[a]
Hemangiomas[a]	Chronic myelogenous leukemia[a]
Malignant carcinoid tumor[a]	Crohn's disease[d]
Chronic granulomatous disease[b]	Diabetic retinopathy[d]
Cervical intraepithelial neoplasia[c]	Multiple sclerosis[c]
Carcinoid tumors[d]	Mycosis fungoides[d]
Ovarian cancer[d]	Polycythemia vera[d]
Skin cancer[d]	Thrombocytosis[d]

a) IFN-α, approval in the USA and/or other countries.
b) IFN-γ, approval in the USA and other countries.
c) IFN-β, approval in the USA and/or other countries.
d) IFN-α, not approved.

generally to treat many viral diseases. However, remarkably, virtually every class of viruses has one or more members that are sensitive to interferon in culture or in animals (Table 10). This leaves open the possibility that most viral diseases will be able to be prevented and/or treated with an appropriate interferon.

The interferons have been useful in the treatment of hepatitis. Specifically, the IFN-α species have been used effectively and are approved for the treatment of chronic hepatitis B (Haria and Benfield 1995; Woo and Burnakis 1997; Grob 1998; Marques et al. 1998; Mazzella et al. 1999; Alberti et al. 2002; Perrillo 2002) and hepatitis C (Vithanomsat et al. 1984; Yamamoto et al. 1992; Davis 1994; Iino et al. 1994; Trepo et al. 1994; Weiland 1994; Haria and Benfield 1995; Roffi et al. 1995; Romeo et al. 1995; Saracco and Rizzetto 1995; Zein and Rakela 1995; Jonas 1996; Alberti et al. 1997; Cooksley et al. 1997; Woo and Burnakis 1997; Hanley and Haydon 1998; Barnes et al. 1999; Shiffman 1999; Markland et al. 2000; Pianko and McHutchison 2000; Yasuda et al. 2000; Diamond and Harris 2001; Hu et al. 2001; Lyra and Di Bisceglie 2001; Sagmeister et al. 2001; Wilkinson 2001; Hino et al. 2002; Katze et al. 2002; Anderson and Rahal 2002). Certain strains of hepatitis C virus are more resistant to treatment than others. These can be identified by genotyping the strains (Martell et al. 1992; Okamoto et al. 1992; Hino et al. 1994; Tsubota et al. 1994; Enomoto and Sato 1995a, 1995b; Enomoto et al. 1995, 1996; Gale et al. 1997; Arens 2001). Studies have correlated a region of the hepatitis C viral nonstructural protein 5A (NS5A) with sensitivity and resistance to interferon. Protein NS5A was found to repress interferon-induced protein kinase, PKR, which is one of the mediators of antiviral activity of interferon. Furthermore, it has been possible to begin to correlate single nucleotide polymorphisms in patients with hepatitis C with their ability to respond to interferon (Hijikata et al. 2001). This will probably be improved immensely in the next few years.

Although interferon has been approved for the treatment of few other infectious diseases (e.g. condyloma acuminatum (Rockley and Tyring 1995), genital warts caused by human papilloma virus type 6 and 11, and labial and genital herpes (Ophir et al. 1995; Glezerman et al. 1988)), it has been shown to be effective for the treatment of laryngeal papillomatosis (Deunas et al. 1997; Haglund et al. 1981; Lundquist et al. 1984) and the prevention of common colds produced by rhinoviruses (Scott et al. 1982; Hayden and Gwaltney 1983; Phillpotts et al. 1983, 1984; Hayden et al. 1986; Higgins et al. 1986), although it has not been approved for these and other viral diseases. Very probably the type I interferons would be efficacious in the treatment and prevention of many viral diseases once appropriate delivery systems have been developed. Moreover, it has been suggested that interferon will be used for many infectious diseases in the future because it has potent immunomodulatory activities (Masihi 2000, 2001). That fact that interferon is active in blocking propagation of all classes of viruses (see Table 10) is tantalizing and may suggest that it will take some novel initiatives to make better use of the interferons to treat viral diseases, e.g. IFN-α is effective in substantially inhibiting retroviruses in tissue culture (Sen et al. 1984; Sperber et al. 1992), but has little effect in the treatment of diseases caused by retroviruses such as HIV – a paradox that has not been adequately addressed.

IFN-β has been found to be effective in relapsing–remitting multiple sclerosis (Silberberg 1994; Goodin 2001; Calabresi 2002; Keegan and Noseworthy 2002; Wingerchuk and Noseworthy 2002) and is currently approved for treatment. Various preparations of IFN-β are in use and all are effective, although no treatment can eliminate the disease. The mechanism by which interferon works is not clear, but it was suggested that IFN-β inhibits migration of activated T cells into the central nervous system (Leppert et al. 1996).

The detailed biological effector mechanisms that result in the various activities of the interferons are surprisingly not defined in most cases. What has made this exceptionally difficult is that the mechanisms vary from animal species to species and from one cell type to another even in the same species. It is clear that the Jak–Stat pathway is involved in many of the mechanisms, as demonstrated by analysis of mice deficient in various components of this pathway, e.g. Stat1 is required for protection of mice from microbial and viral pathogens (Durbin et al. 1996; Meraz et al. 1996). However, the downstream events required for protection against specific viruses and other pathogens is still not

Table 10 *Effect of interferons on viral propagation and in patients*

Virus family	Inhibited by interferons	Major viruses studied with interferon	References
Picornaviridae	Yes	Rhinovirus, cardiovirus (encephalomyocarditis virus)	Scott et al. (1982); Hayden and Gwaltney (1983); Phillpotts et al. (1983, 1984); Hayden et al. (1986); Higgins et al. (1986); Sperber et al. (1993b); Soh et al. (1994c); Yasuda et al. (2000)

defined, and the mechanisms differ from virus to virus. Furthermore, it is becoming increasingly clear that other pathways independent of the Jak–Stat pathway can initiate signal transduction by the type I interferons, e.g. cells from mice lacking Stat1 can still respond to type I interferons: IFN-α and IFN-β can modulate proliferative responses in phagocytes from Stat1-deficient mice (Gil et al. 2001). Understanding of these events is further complicated by the multiplicity of the type I interferons (see Table 6) that exhibit different activities (see Tables 3-5), although they interact with the same receptor. This is an area that needs to be explored in great detail to understand this family of proteins and their mechanisms of action.

The side effects of most biotherapeutics are significant and limit the dose of most cytokines. Interferon is not an exception, with side effects that often require reducing dosage or ceasing treatment (Nathan et al. 2002; Raanani and Ben Bassat 2002). So far the mechanisms by which interferons produce side effects have not been determined. It would be a major advance to have interferon molecules with little or no toxicity.

Patients treated with protein molecules often develop serum antibodies. If the antibodies neutralize the activity of the proteins, they can cause a relapse. This has been shown in many diseases treated with interferons (Nolte et al. 1994; Antonelli et al. 1997; Dianzani and Pestka 1997; Viscomi et al. 1999).

In carrying out clinical trials with interferons, it is useful to follow the activity in patients and in culture by biological assays. A number of these have been developed (Meager 2002), but no single assay or set of assays currently provides a standard assessment of activity in patients. Many molecules have been reported to stimulate production of interferons and other cytokines. One of these, imiquimod, has been approved as a topical agent for the treatment of external and anal genital warts (Dockrell and Kinghorn 2001).

As noted above, interferon is already used extensively for a wide range of diseases. Nevertheless, because the type I interferons have broad activities, it is likely that they will be used to a greater extent in the future, e.g. these interferons activate cytotoxicity of many cells of the immune system such as NK cells, T cells, macrophages, and dendritic cells (Herberman et al. 1981, 1982a, 1982b; Ortaldo et al. 1982, 1983a, 1983b; Li et al. 1990). Interferon has enormous anti-angiogenic activity, perhaps, the highest activity of any known biotherapeutic (White et al. 1989; Appelbaum 1990; White 1990; Kaban et al. 1999; Ozawa et al. 2001). Furthermore, interferons enhance the expression of tumor-associated antigens on the cell surface of cells enormously in culture and in patients (Greiner et al. 1984, 1985, 1987, 1992; Ozzello et al. 1995). This increase in the surface expression of the tumor-associated antigens often turns the heterogeneous population of tumor cells with low levels of the antigens and few cells carrying these surface antigens into a population of cells that are all expressing these surface tumor antigens. The cells are, therefore, recognized more efficiently by the immune system and by cytotoxic cells activated to destroy cells expressing these antigens. Together with the direct antiproliferative activity of interferons on the tumor cells, all these actions make interferon a most promising agent to treat cancers in general. The challenge is to be able to use this enormous potential of the interferons without the debilitating side effects. Appropriate technology to localize the interferons in tumors could overcome the problem of systemic side effects. Overall, it is highly likely that interferon will play a major role in the next generation of novel antitumor and antiviral therapies.

ACKNOWLEDGMENTS

For the work done in my laboratory discussed in this chapter, I thank my many colleagues who have carried out the studies cited. I thank Ellen Feibel for her diligent assistance in the preparation of this manuscript. This author's work was supported in part by US Public Health Services Grants RO1-CA46465 from the National Cancer Institute and RO1 AI36450 and RO1 AI43369 from the National Institute of Allergy and Infectious Diseases.

Cytokines

SERGIO ROMAGNANI

Growth factors for hemopoietic precursors, myeloid cells, and thrombocytes 1
Growth and differentiation factors for lymphoid cells 7
Proinflammatory cytokines 12
Anti-inflammatory and regulatory cytokines 20
References 25

Cytokines are important signaling molecules produced by cells involved in inflammation, immunity, differentiation, cell division, fibrosis repair, and many other functions. Although cytokines share properties in common with hormones that are produced continuously and interact with them, there are also notable distinctions. Hormones are typically produced by specialized cells and released into the bloodstream and so can act at a distance from the source, in an 'endocrine fashion'. In contrast, cytokines usually act at short range, a few cell diameters apart, as in a 'paracrine' or 'autocrine' manner. The major differences between hormones and cytokines are summarized in Figure 1.

Today, we are confronted by considerably more than 100 cytokines as structurally identified molecules (Oppenheim and Feldman 2000). A great proportion of these molecules have recently been characterized because of their chemotactic activity and, therefore, they have been named as chemotactic cytokines or chemokines (Zlotnik and Yoshie 2000). These are considered separately (see Chemokines). Some other cytokines are not discussed here, because either they mainly act as membrane rather than soluble signals or their activity is only minimally involved in the function of the immune system. Usually cytokines are grouped in different families according to structural similarity of ligands and/or receptors. Despite the fact that the same cytokine may exhibit different functions and that the same function may be exerted by different cytokines, we have tried to group cytokines into five different families based on their most impressive or better-known function (Table 1). This type of classification is certainly arbitrary and questionable, but it may be of some usefulness from a didactic point of view.

GROWTH FACTORS FOR HEMOPOIETIC PRECURSORS, MYELOID CELLS, AND THROMBOCYTES

Definitive hemopoiesis is a complex cellular process that is regulated, in part, by hemopoietic growth factors (HGF) and the bone marrow microenvironment, which act to promote the survival, proliferation, and differentiation of hemopoietic stem cells (SC) and their progeny. HGFs are produced by accessory or stromal cells (macrophages, fibroblasts, endothelial cells, and adipocytes) in the bone marrow and elsewhere, and interact with specific receptors expressed on hemopoietic cells.

Stem cell factor

The main HGF is stem cell factor (SCF). SCF is also known as steel factor (SF), because it was mapped to the Sl locus, Kit ligand (KL), and mast cell growth factor (MCGF) (Lyman and Jacobsen 1998). SCF is produced in both soluble and membrane-bound forms. These isoforms arise from two differentially spliced complementary DNAs (cDNA). One cDNA encodes a precursor of 273 amino acids that contains a cleavable N-terminal signal peptide of 25 amino acids and gives rise to the transmembrane protein with 248 amino acids. The gene for SCF might be located on the distal end of

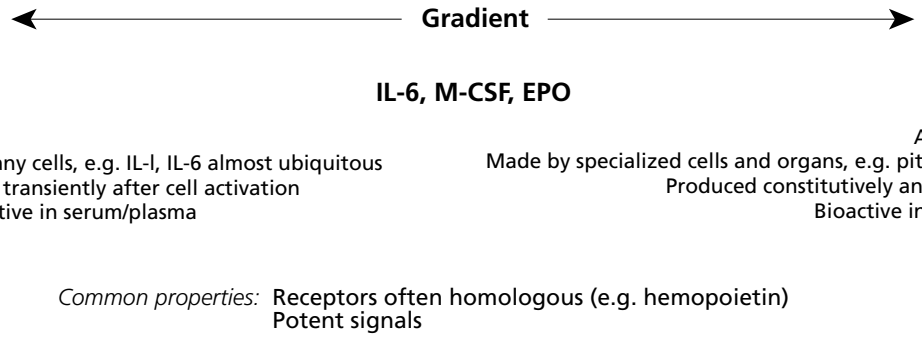

Figure 1 *Differences between cytokines and hormones. EPO, erythropoietin; IL, interleukin; M-CSF, macrophage colony-stimulating factor. (Redrawn from Oppenheim and Feldman 2000, with permission.)*

the long arm of human chromosome 12 (Keller and Linnekin 2000).

Analysis of the expression of the gene for SCF in the developing embryo suggests that this gene has multiple functional roles in development, e.g. the gene for SCF is expressed along the migratory pathways for stem cells that give rise to hemopoietic, melanocyte, and germ-cell lineages. Specifically, SCF has been detected in the genital ridge of day 10 embryos, whereas its receptor (SCFR) is expressed in the migrating germ cells. SCF expression in the genital ridge decreases early after the beginning of gestation, but remains high in the developing gonads during sexual differentiation (both in the testes and in the ovary). This pattern of expression suggests that SCF is involved in regulating the migration, proliferation, and differentiation of germ cells (Matsui et al. 1990). Moreover, SCF is expressed in mesenchymal cells located in the limb bud where melanocyte precursors colonize, whereas SCFR is expressed on the migrating cells. The expression of SCF persists during and after stem cell colonization of the limb buds. SCF is also expressed in fetal liver, which is the migratory site for hemopoietic SCs in the developing embryo. As would be predicted, there is a marked reduction in the number of SCFR-positive SCs that migrate to the fetal livers of Sl/Sl embryos (mutants that have deletion of the transmembrane and cytoplasmic domains of SCG). SCF mRNA transcripts have also been detected in other tissues in the developing embryo, including the spinal cord, forebrain, cerebellum, and olfactory bulbs, suggesting that SCF might play a role in the developing CNS. Although there are no gross neurological defects in Sl mutant mice, Sl/Sl mutant mice show a defect in hippocampus-dependent learning (spatial learning). In the adult, SCF is expressed by stromal or accessory cells (endothelial cells, monocytes, and fibroblasts) in the adult, where these cells constitute the hemopoietic microenvironment (Broudy 1997). SCF is also produced by intestinal epithelial cells, Sertoli cells, and follicular cells that surround oocytes in the gonads, thymic stroma, and brain cells, including those that constitute the olfactory bulb, thalamus, cerebellum, and brain. SCF expression has also been detected in human $CD34^+$ cells and keratinocytes in the skin (Ratajczak et al. 1995).

Stem cell factor plays an essential role in the survival, growth, and differentiation of cells responsible for hemo-

poietic, germ-cell, and melanocyte cell development during both embryonic development and adult life In particular, SCF is essential for the migration and homing of SCs to their appropriate developmental sites; moreover, SCF directly promotes the survival of these stem-cell populations (Keller and Linnekin 2000).

The receptor for SCF, SCFR, is expressed on most hemopoietic progenitors but is not expressed on their differentiated progeny, including mature myeloid and monocytic cells or lymphoid and erythroid cell populations; however, its expression is maintained at high levels on mast cells. In this regard, SCF promotes the survival, proliferation, and differentiation of mast cells in vitro. In addition, SCF, in combination with the interleukin (IL)-3 and IL-4, promotes the proliferation of mast cells and their progenitors. SCF can promote the adhesion of mast cells, hemopoietic progenitor cells, and cell lines to fibronectin or vascular cell adhesion molecule 1 (VCAM-1) expressed on endothelial cells by activating VLA-4 and VLA-5 integrin expression on progenitor cells. A single injection of SCF to normal mice promotes a dose-dependent increase in total number of peripheral blood leukocytes, including neutrophils and immature myeloid cells, but not circulating platelets or red cells (Galli et al. 1994). The in vivo hemopoietic effects of SCF are summarized in Table 2.

Although no abnormalities involving the SCF genetic loci have been reported, locally high concentrations of soluble SCF have been found in lesions of human cutaneous mastocytosis. This disease is characterized by accumulations of mast cells, as well as increases in the production of epidermal melanin similar to that observed in transgenic animals which expressed SCF transgenes in keratinocytes. This has led to the hypothesis that locally produced SCF can promote mast cell hyperplasia (Keller and Linnekin 2000).

Colony-stimulating factors

Hemopoietic activity is also the main activity of the so-called colony-stimulating factors (CSF). CSFs comprise four cytokines, named multi-CSF or IL-3, granulocyte (G)-CSF, CSF-1 or macrophage (M)-CSF, and granulocyte–macrophage (GM)-CSF. The major activity of CSFs is the development of colonies from precursors of the granulocyte and monocyte–macrophage lineage.

INTERLEUKIN 3

IL-3, also known as multi-CSF, is a typical member of the family of four helix-bundle cytokines. The mature human IL-3 is a polypeptide of 133 amino acids and the mature murine IL-3 has 140 amino acids. The human gene for IL-3 is on chromosome 5q21 (Schrader 2000).

IL-3 is synthesized and released by antigen-activated T lymphocytes, as well as by mast cells and eosinophils following antigen crosslinking of cytophilic antibodies bound to Fc receptors present on their surface (Schrader 2000).

IL-3 stimulates the growth, differentiation, and survival of pluripotential hemopoietic SCs and many of their progeny, including multipotential progenitors and progenitors committed to individual cell lineages and mature cells (Bukowski et al. 1996). These include SCs able to originate all lymphohemopoietic cell lineages and multipotential progenitors capable of generating neutrophils, macrophages, megakaryocytes, and erythroid cells. More committed progenitors targeted by IL-3 include those giving rise to in vitro colonies of eosinophils, neutrophils, macrophages, megakaryocytes, mast cells, and erythroid cells. IL-3 also supports the survival of mature mast cells, eosinophils, basophils, and megakaryocytes, and also augments the effector functions of basophils, mast cells, and eosinophils.

The effects of IL-3 depend on where it is released. The local release of IL-3 in mucosal surfaces or in lymph nodes results in the generation of mucosa-type mast cells from undifferentiated, committed, mast-cell progenitors present in these tissues. Systemic release of IL-3 results in increases in the number of hemopoietic progenitor cells and mast cell precursors in the spleen, as well as increases in megakaryocytes, neutrophils, and mast cells.

IL-3 appears to have a role in the response to certain parasites, probably because of its ability to increase the numbers of infection-stimulated mast cells and basophils. Administration of recombinant IL-3 by subcutaneous injection increases the levels of neutrophils and eosinophils, as well platelet counts, lymphocyte numbers and numbers of $CD34^+$ cells in the peripheral blood

(Schrader 2000). Side effects induced by IL-3 include headaches, flu-like symptoms, fever, and rashes. In general, clinical application of IL-3 has been poor.

G-CSF

G-CSF is a 25-kDa glycoprotein that regulates production of neutrophilic granulocytes, and activates mature neutrophils. Its gene is located on human chromosome 17q21-q22 (Nagata 2000).

Monocytes, macrophages, endothelial cells, and fibroblasts are induced to express G-CSF by various stimuli (Metcalf and Nicola 1985). Some carcinoma cells and tumor cell lines produce G-CSF constitutively. G-CSF has a unique receptor which mediates colony formation of neutrophilic granulocytes in semi-solid cultures of bone marrow cells.

Unlike other CSFs, such as GM-CSF and IL-3, G-CSF is rather specific to progenitor cells of neutrophilic granulocytes (Nicolas et al. 1983). G-CSF not only stimulates proliferation and differentiation of progenitors, but also prolongs the survival of mature neutrophils and enhances their functional capacity. Mice lacking the G-CSF gene show chronic neutropenia (Figure 2), are deficient in granulocyte and macrophage progenitor cells, and show impaired neutrophil mobilization (Lieschke et al. 1994; Basu et al. 2002), whereas administration of G-CSF causes increase in granulocyte numbers (Welte et al. 1987) and long-term exposure to

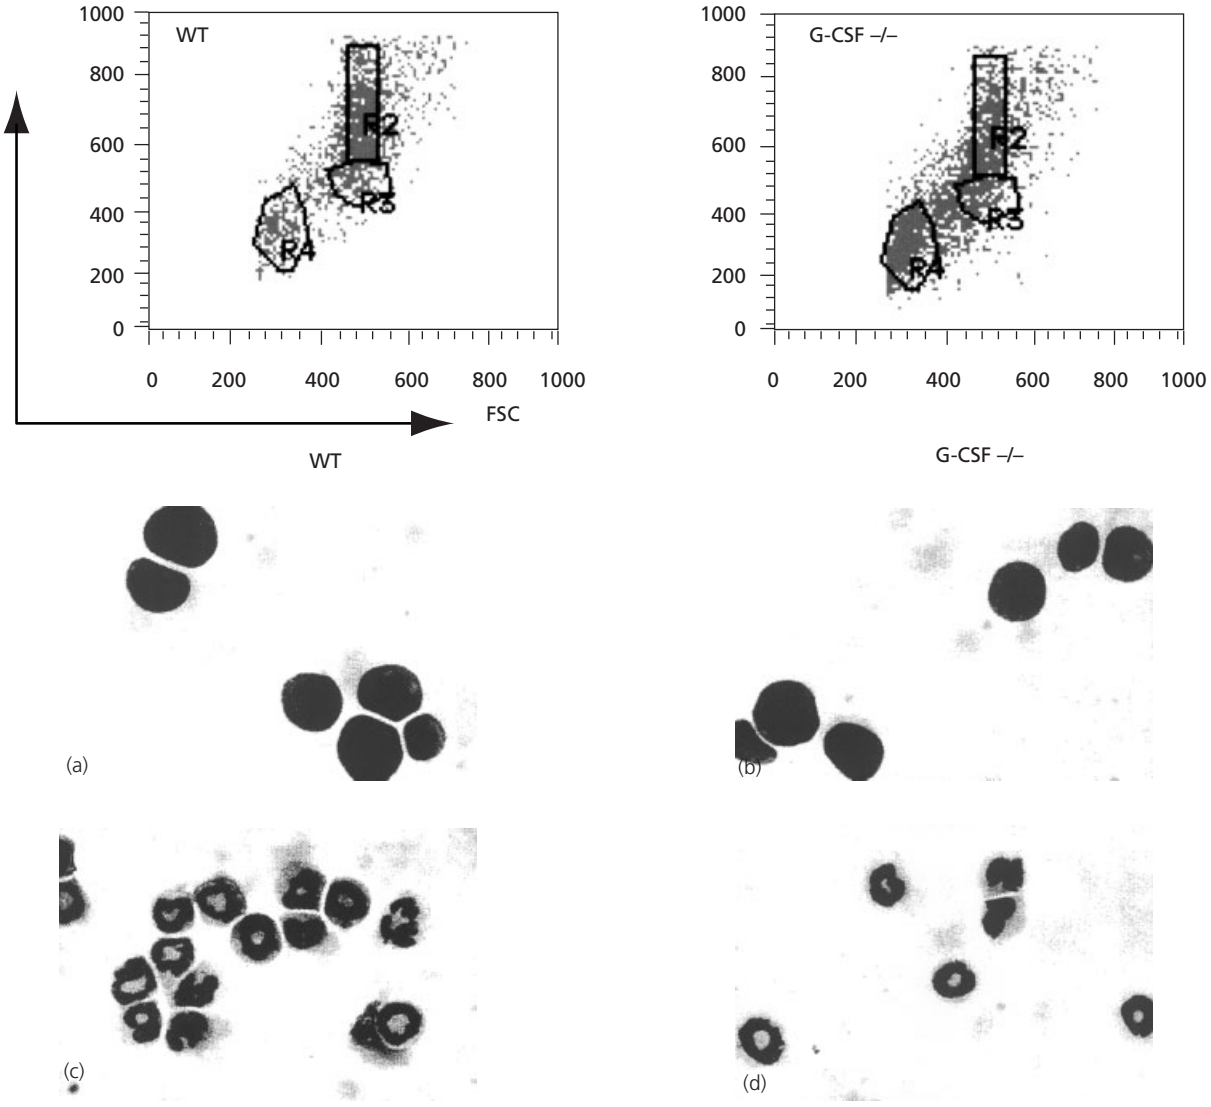

Figure 2 *Essential role of G-CSF in neutrophil development. G-CSF of transgenic mice causes sustained granulocytosis (Chang et al. 1989).

G-CSF is effectively used to stimulate granulopoiesis in neutropenic patients. G-CSF is also being administered to patients with cancer receiving chemotherapy or radiotherapy with or without bone marrow transplantation, to patients receiving immunosuppressive agents after organ transplantation, and to patients with cyclic neutropenia. In these last patients, without altering the cyclic nature of this disease, G-CSF elevates neutrophil levels during the nadir phase and therefore prevents many of the symptoms of the disease (Nagata 2000).

M-CSF

M-CSF, initially known as CSF-1, is a 80- to 100-kDa glycoprotein or 130- to 160-kDa chondroitin sulfate-containing proteoglycan, or it is expressed as a membrane-spanning 68- to 86-kDa glycoprotein on the surface of cells. The human M-CSF gene is approximately 21 kilobases (kb) in length, comprising 10 exons, and is localized to human chromosome 1p13-p21 (Stanley 1994).

M-CSF is expressed in most tissues, including submaxillary gland, lung, spleen, kidney, lymph nodes, brain, liver, testis, and ovary. Several types of normal cells synthesize M-CSF, including fibroblasts, endothelial cells, bone marrow stromal cells, osteoblasts, thymic epithelial cells, keratinocytes, astrocytes, myoblasts, mesothelial cells, liver parenchymal cells, thyrocytes, and adipocytes. M-CSF is also synthesized by ovarian granulosa cells, oviduct epithelium, and in large amounts by uterine epithelial cells during pregnancy (Arceci et al. 1992).

M-CSF is the primary regulator of the survival, proliferation, and differentiation of mononuclear phagocytes, including tissue macrophages and osteoclasts. It has also been shown to stimulate $CD5^+$ B lymphocytes to develop into biphenotypic B/macrophage cells. Cells requiring M-CSF for their development may regulate, via tropic and/or scavenger functions, bone resorption, male fertility, the thickness of the dermis, and neural processing. In the female reproductive system, M-CSF regulates the development of macrophages and the function of nonmononuclear phagocytic cells.

GM-CSF

GM-CSF is a protein of 144 amino acids, containing a leader sequence of 17 amino acids, two intramolecular disulfide bonds, and two potential sites of *N*-glycosylation, as well as sites of *O*-glycosylation. The apparent molecular weight of the mature glycosylated proteins is 13 kDa. The GM-CSF gene maps to chromosome 5q31.1 (Nicolas 2000) and it is very tightly linked to the IL-3 gene. There is also a cluster of cytokine (M-CSF, IL-4, IL-5) and receptor (*c-fms*) genes in the same area.

GM-CSF is a product of activated T lymphocytes, fibroblasts, endothelial cells, macrophages, and stromal cells, but also B lymphocytes, mast cells, eosinophils, blast cells, and osteoblasts. The major stimulant for T-cell production of GM-CSF is engagement of the T-cell receptor (TCR) (TCR) by antigen. In addition, the cytokines IL-1 and IL-2 and infection with the human T-cell lymphotropic virus (HTLV) also increase GM-CSF production by T cells. For B lymphocytes, antigen receptor activation (e.g. by *Staphylococcus aureus*) and bacterial lipopolysaccharide (LPS) or phorbol esters induce GM-CSF synthesis. For mast cells, degranulating agents, such as anti-IgE and calcium ionophores and, for osteoblasts, LPS and parathyroid hormone, are effective. For macrophages, fibroblasts, and endothelial cells, the major inducers of GM-CSF synthesis are LPS, IL-1, and tumor necrosis factor (TNF), as well as phorbol esters (Metcalf and Nicola 1995).

The effects of injected GM-CSF consist of a rapid and profound decrease in white blood cell counts, resulting from sequestration within the lungs followed by a progressive rise in circulating neutrophils, eosinophils, monocytes, and progenitor cells for all lineages (colony-forming cells) (Metcalf and Nicola 1995). These rises are, however, significantly less than those seen with injected G-CSF. GM-CSF has also been used to mobilize hemopoietic SCs into the peripheral blood for subsequent autologous bone marrow transplantation (ABMT). Such SCs induce a more rapid recovery of both neutrophils and platelets than is achieved by ABMT, but G-CSF exhibits a greater mobilizing efficiency than GM-CSF even for this purpose. Some studies have begun to appear in human beings evaluating the use of GM-CSF as an antiviral vaccine adjuvant for immunization against hepatitis B and influenza, with encouraging but preliminary results. Trials have also been initiated in which GM-CSF is administered after surgical resection of melanoma tumors or with passive (antimelanoma or antineuroblastoma antibodies) or active (autologous melanoma cells with BCG) immunization against tumor cells (Nicolas 2000).

Interleukin 5

IL-5 is an important growth and differentiation factor for eosinophil granulocytes. It is a glycoprotein with an M_r of 45 kDa and is unusual among the T-cell-produced cytokines in being a disulfide-linked homodimer (Gretchen et al. 2000). It is the most highly conserved member of a group of evolutionally related cytokines, including IL-3, IL-4, IL-13, and GM-CSF, which are closely linked on human chromosome 5.

T cells are an important source of the cytokine (Sanderson 1992). However, IL-5 mRNA production has also been demonstrated in mast-cell lines and human Epstein–Barr virus (EBV)-transformed B cells. Furthermore, eosinophils themselves have been demonstrated to produce IL-5 (Broide et al. 1992).

IL-5 plays a unique and specific role in the control of eosinophil production and differentiation (eosinophil differentiating factor (EDF)). It is also able to activate basophils, but is probably not the major factor controlling basophil production. The effect on eosinophil production is relatively direct. When IL-5 is expressed, eosinophils are produced, and when IL-5 expression is inhibited by drugs or gene knock-out eosinophil production and survival virtually cease. The role of IL-5 in eosinophilia (Figure 3), coupled with a better understanding of the part played by eosinophils in the development of tissue damage in chronic allergy, has made IL-5 a major target for a new generation of antiallergic drugs (Schwenger et al. 2000).

Interleukin 11

IL-11 is an important growth factor for thrombocytes. The mature IL-11 protein is a highly conserved, cationic protein of 178 amino acids. The IL-11 gene consists of five exons and four introns which contain 7 kilobase-pairs (kbp) of genomic DNA. The gene for IL-11 has been localized to the long arm of chromosome 19 at band 19q13.3–q13.4. The IL-11 gene is in close proximity to the gene that codes for the subunit of protein kinase

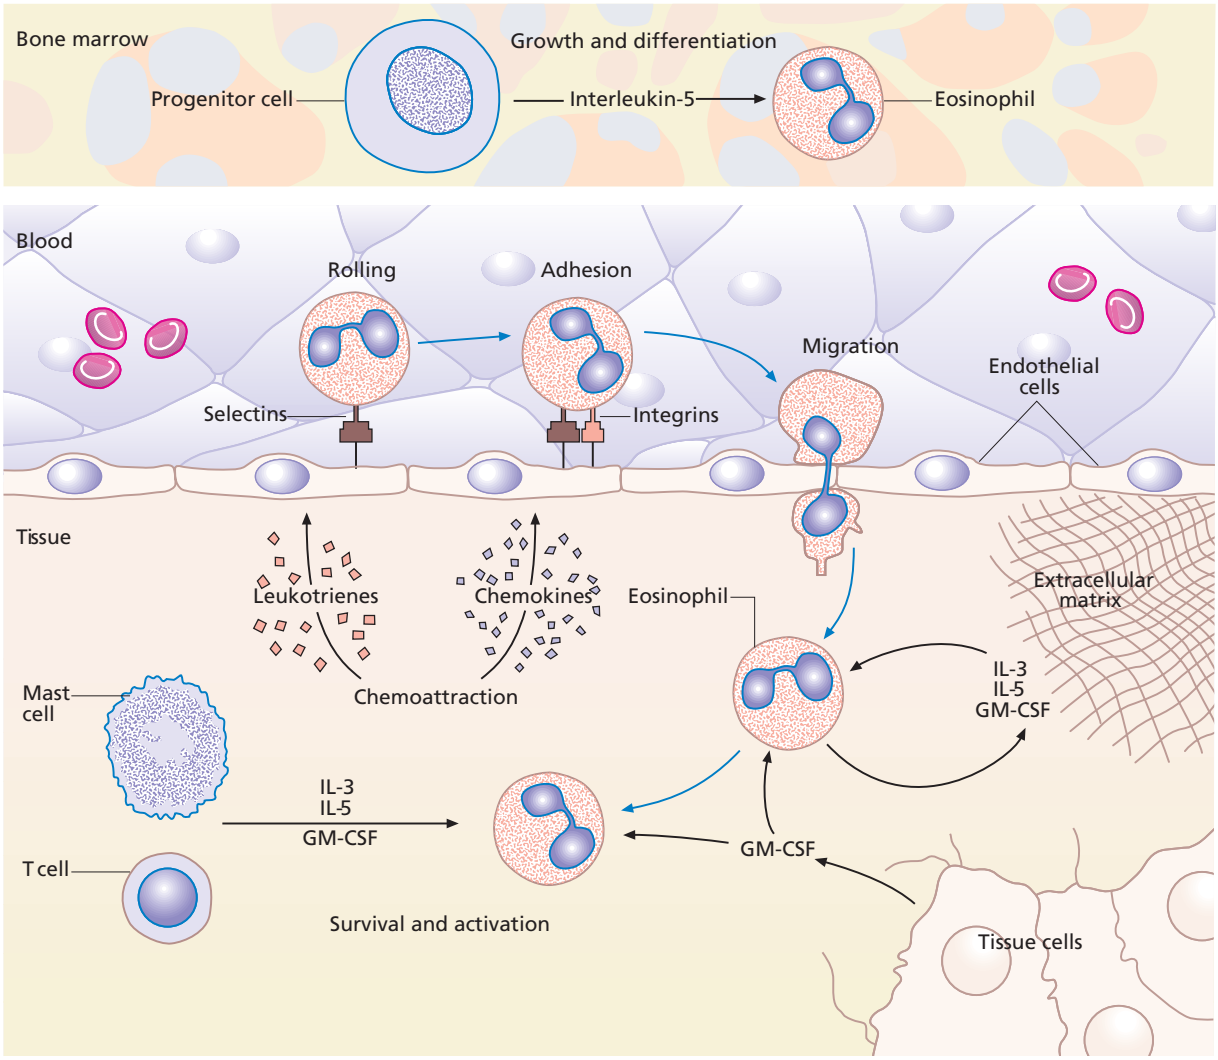

Figure 3 *Different activities of interleukin IL-5 on eosinophil granulocytes and in processes involved in eosinophilia. Eosinophilia develops in the bone marrow in response to the stimulation of progenitor cells by IL-5. Mature eosinophils in the blood adhere to endothelial cells through the interaction of selectins and integrins with endothelial receptors for these molecules. On exposure to chemoattractant mediators, eosinophils undergo diapedesis between endothelial cells and migrate into the tissues. The accumulation of eosinophils is regulated by the generation and survival and activation factors (IL-3, IL-5, and granulocyte–macrophage colony-stimulating factor [GM-CSF]) by T cells and mast cells. In response to extracellular matrix components, eosinophils themselves can also generate the cytokines and prolong their survival. (Redrawn from Rothenberg 1998, with permission.)*

C, as well as the genes for several zinc finger proteins (Keith 2000).

Basal and inducible IL-11 mRNA expression can be detected in fibroblasts, epithelial cells, chondrocytes, synoviocytes, keratinocytes, endothelial cells, osteoblasts, and certain tumor cells and cell lines (Table 3).

IL-11 has several activities. Human IL-11, in synergy with IL-3, IL-4, IL-6, or SCF, supports murine primitive hemopoietic cell. IL-11 can induce production of the same acute phase proteins (APP) as IL-6. IL-11 also acts on adipocytes and osteoclasts, and reduces proinflammatory mediator production by LPS-activated macrophages. IL-11 plasma levels are significantly elevated in patients with severe thrombocytopenia secondary to myeloablative therapy or in those with immune thrombocytopenia. Platelet counts and endogenous IL-11 levels after myeloablative therapy were inversely related. Therefore, it is suggested that induction of IL-11 expression is a physiological response to thrombocytopenia in humans and that IL-11 plays a role in the regulation of megakaryocytopoiesis and thrombopoiesis during acute thrombocytopenia (Goldman 1995). Although administration of IL-11 as a single agent to normal animals primarily stimulated megakaryocytopoiesis and thrombopoiesis, in myelosuppressed animals IL-11 stimulated multilineage recovery of hemopoietic progenitor cells. Mice receiving subcutaneous human IL-11 before whole-body radiation exposure had increased numbers of surviving crypts. IL-11 produces intestinal mucosal tropic effects in rats with experimental short bowel syndrome. Administration of IL-11 was also shown to enhance survival in a murine model of radiation-induced pulmonary injury (radiation pneumonitis). IL-11 has been recently approved for use in the prevention of the severe thrombocytopenia that occurs after cancer chemotherapy. Studies of cells and tissues from other organ systems indicate that IL-11 is active in protection and restoration of the gastrointestinal mucosa, and has major effects as an immunomodulating agent as well as activity in bone metabolism (Keith 2000).

Table 3 *Tissue/cell types expressing interleukin IL-11*

Tissue	Cell type/cell lines
CNS	Hippocampal neurons
	Spinal motor and sympathetic neurons
	Astrocytic glioblastoma
Thymus	Myeloid? (T2)
Lung	Fibroblasts, epithelial cells
Muscle cells	
Bone	Fibroblasts, osteosarcoma cell lines, osteoblasts
Connective tissues	Chondrocytes, synoviocytes

GROWTH AND DIFFERENTIATION FACTORS FOR LYMPHOID CELLS

Interleukin 2

IL-2 was the first interleukin to be identified and characterized at the molecular level. IL-2 is a small (15.5 kDa) globular glycoprotein of 133 amino acids. The IL-2 gene is located in chromosome 4, band q28 (Smith 2000).

For a long time, the only cells known to express the IL-2 gene following antigen or polyclonal stimulation were T cells (Smith 1980). More recently, however, dendritic cells have also been shown to express the IL-2 gene (Granucci et al. 2003). Of note, IL-2 shares a receptor chain (γc) with other cytokines, i.e. IL-4, IL-7, IL-9, IL-15, and IL-21 (Figure 4), whereas its α chain (known as TAC) is specific.

One of the major activities of IL-2 is to promote the clonal expansion of both $CD4^+$ T-helper (Th) cells

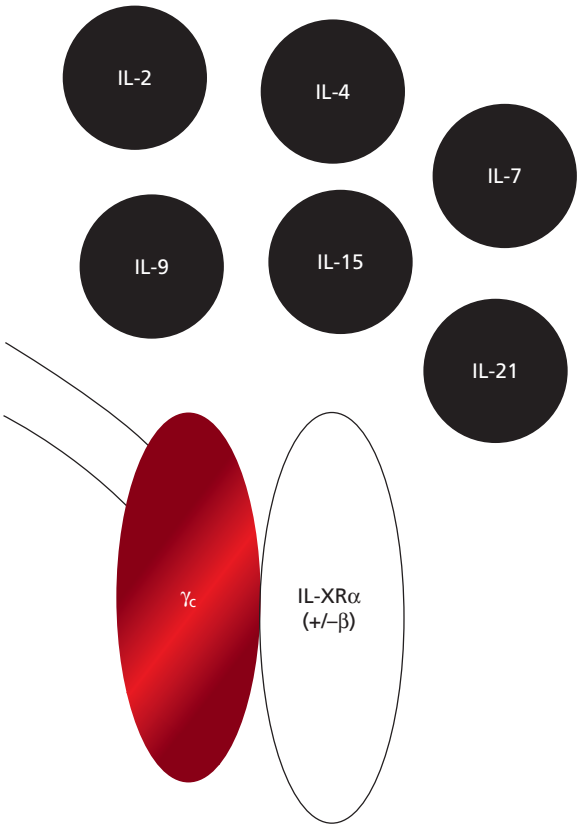

Figure 4 *Interleukins IL-2, IL-4, IL-7, IL-9, and IL-15 share the γ chain of their receptor. (Modified from Fry and Mackall 2002.)*

and $CD8^+$ cytotoxic T lymphocytes (CTLs). IL-2 is obligatory for the generation of both type 1 T-helper (Th1) and type 2 (Th2) cells and potentiates the production of the characteristic cytokines released by these differentiated Th cell subsets. IL-2 also synergizes with both interferon-γ (IFN-γ) and IL-12 in augmenting natural killer (NK) cell cytolytic activity. In addition, IL-2 also triggers the feedback downregulation of the expanded, differentiated effector cells. First, IL-2 is produced only transiently after antigen activation and, therefore, its positive effects rapidly disappear. Second, IL-2 withdrawal results in apoptosis, so that many of the antigen-specific effector cells are deleted as soon as there is no longer any antigen-induced IL-2 production. There are also other ways in which IL-2 gives negative signals. One is via the IL-2-promoted expression of CTLA-4, a negative regulator of T-cell receptor signals, which competes with the positive, costimulatory molecule, CD28. Thus, instead of leading to continuous cytokine production, the IL-2-promoted expression of CTLA-4 results in suppression of IL-2 gene expression. Also, IL-2 promotes the expression of Fas ligand (FasL), which activates programmed cell death via Fas, expressed to a greater extent on antigen-activated $CD4^+$ T cells (Smith 2000).

Deletion of the IL-2 gene has no effect on lymphocyte development, so that at birth IL-2 knock-out mice have normal numbers of T cells, B cells, and NK cells in both primary and secondary lymphoid compartments. However, during postnatal development a progressive lymphoid hyperplasia occurs, and cells accumulate in the secondary lymphoid tissues with an activated surface phenotype. Concomitantly, an autoimmune hemolytic anemia ensues, and mice begin to die from anemia within the first few weeks of life. Mice surviving beyond this initial phase subsequently develop colonic enteritis (Schorle et al. 1991)

IL-2 has been the first interleukin to be used therapeutically in patients with cancer. IL-2 was initially administered in these patients at very high doses intravenously. This kind of treatment regimen resulted in severe systemic toxicity ('cytokine syndrome'). IL-2 therapy results in an antitumor response in about 15 percent of individuals suffering from renal cell carcinoma, with about 10 percent of individuals achieving a long-term, complete response (Rosenberg et al. 1987), but the mechanisms responsible for this antitumor response still remain obscure, even after 15 years of IL-2 therapy. More recently, IL-2 has been used in the treatment of individuals infected with HIV (Kovacs et al. 1996). The use of the anti-TAC monoclonal antibody to prevent IL-2 binding to its high-affinity receptor, has recently been shown to be an effective immunosuppressant therapy for the prevention of allograft rejection (Vincenti et al. 1998). Accordingly, all of these approaches underscore the central role of IL-2 in the generation of an effective immune response, and the effectiveness of immunosuppressive therapies that block either IL-2 production or activity.

Interleukin 4

IL-4 is a 20-kDa secreted glycoprotein. The IL-4 gene resides on the long arm of chromosome 5 at position 5q21 within a complex that contains genes for other cytokines. The IL-4 gene is closely linked to the IL-13 gene, which lies immediately downstream of the IL-4 locus. The gene for another Th2 cytokine, IL-5, is also closely linked. The IL-3 and GM-CSF genes are located in this chromosomal region as well. The close proximity of the cytokines IL-4, IL-13, and IL-5 suggests that there may be some type of locus control to allow for coordinate expressions of these cytokines in Th2 cells (Keegan 2000).

IL-4 expression is induced in T cells and highly induced in differentiated Th2 cells and $NK1.1^+$ T cells in response to stimulation via the TCR. IL-4 message is also expressed in mast cells, basophils, and eosinophils in response to stimulation through the cell surface receptor for IgE.

IL-4 can elicit many diverse biological responses. These responses include costimulation of B-cell and T-cell proliferation, the protection of cells from spontaneous and induced apoptosis, and the regulation of chloride ion transport by intestinal epithelial cells. However, the dominant function of IL-4 is its ability to promote the differentiation of naïve $CD4^+$ T cells into the so-called Th2 profile of cytokine production (Figure 5). As known, Th2 cells secrete a set of cytokines, including IL-4, IL-5, IL-6, IL-10, and IL-13, that tend to favor a phagocyte-independent immune response while suppressing the phagocyte-dependent immune response controlled by Th1 cells. The second dominant function of IL-4 is its ability to drive immunoglobulin class switching to the IgG1 and IgE isotypes in mice and to the IgG4 and IgE isotypes in humans (Paul 1991). The ability of IL-4 to regulate the Th cell phenotype has direct relevance to the outcome of several diseases. Excessive IL-4 production by Th2 cells has been associated with elevated IgE production and allergy. In addition, a strong tendency towards Th2 cell differentiation can result in a failure to cure certain infections efficiently by intracellular pathogens such as *Leishmania major*, and lead to immunopathology. IL-4 also has a number of effects on monocytes. It increases expression of MHC class II molecules and IL-1Ra, while downregulating production of the proinflammatory cytokines, IL-1, TNF-α, IL-6, and IL-8. IL-4 is a growth and survival factor for mast cells. It enhances VCAM-1 expression on endothelial cells and downregulates IL-8 production. IL-4 induces eotaxin production by lung, and calcium ion secretion by gut, epithelial cells (Keegan 2000).

IL-4 has been used to treat a number of disease models in mice. It has been the most successful at

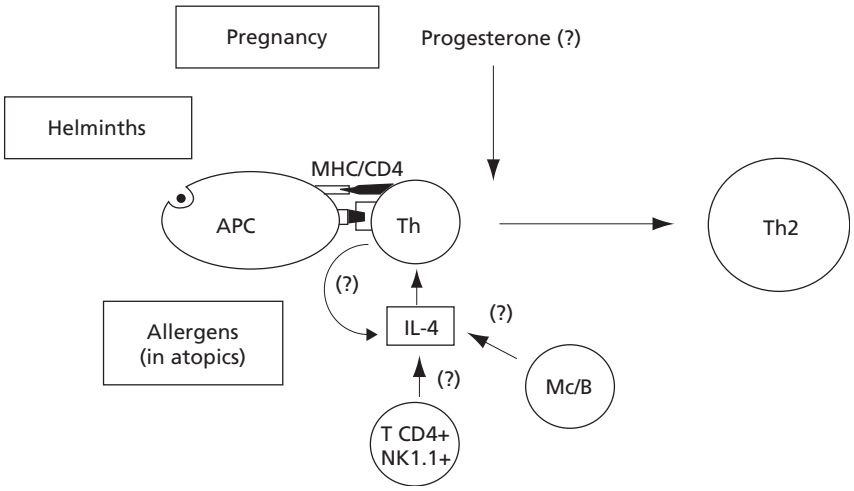

Figure 5 *Role of interleukin IL-4 in the differentiation of naive T-helper (Th) cells into Th2 effectors. IL-4, produced by natural killer NK.1.1$^+$ T cells, mast cells/basophils, but mainly by naïve Th cells themselves, at the beginning of the specific immune response, is required for the differentiation of these last cells into Th2 effectors. APC, antigen-presenting cell. (Redrawn from Romagnani 1998, with permission.)*

ameliorating autoimmune diseases that are caused by activated Th1 cells. IL-4 treatment prevents the development of diabetes in NOD mice, as well the development of experimental autoimmune encephalitis (EAE) or neuritis. Although initially characterized as a growth and survival factor, IL-4 has been shown to suppress the growth of some cancer cells in vivo. This inhibition is seen in the absence of T cells and depends on the infiltration of eosinophil granulocytes and the inhibition of tumor angiogenesis. IL-4 has been used systemically as an aid to cell-based therapy for cancer. Bolus injection of IL-4 results in flu-like symptoms, gastrointestinal upset, asymptomatic liver damage, severe allergy-type symptoms in the nasal mucosa, and vascular leak syndrome. However, IL-4 does not have apparent toxicity if administered locally (Saleh et al. 1999).

Interleukin 7

IL-7 is a single-chain glycoprotein of 25 kDa. The human IL-7 gene is located on chromosome 8, bands q13 (Spits 2000).

The main cell types that express the gene are bone marrow stroma, thymic stroma, intestinal epithelial cells and keratinocytes, mature but not immature dendritic cells, dendritic cells derived from CD34$^+$ cord blood cells cultured with GM-CSF and TNF-α, and platelets (Wiles et al. 1992; Watanabe et al. 1995).

Gene-targeting studies in the mouse have demonstrated that IL-7 is a major factor involved in development of T and B lymphocytes. In humans, IL-7 plays an essential role in the development of T cells (Figure 6).
IL-7 also has effects on human B-cell precursors, but it does not seem to be essential for human B-cell development. Whether IL-7 is actually a growth factor for immature thymocytes is somewhat controversial, but it is well established that IL-7 acts as a growth/maturation factor for human thymocyte precursors. IL-7 has also been reported directly to augment cytolytic activity in human NK cells, even if less efficiently than IL-2. Several reports have documented effects of IL-7 on both development and function of cells of the myeloid lineages. IL-7 also enhances myeloid colony formation from CD34$^+$ cells in vitro and may play a role in the function of mature monocyte–macrophages by inducing secretion of cytokines and increasing tumoricidal activity (Spits 2000).

The activities of IL-7 on T cells have led to the proposal that IL-7 can be used to overcome immunodeficiencies in certain situations by accelerating T-cell development, expanding the pool of newly developed T cells, and promoting functional maturation of T cells. However, more studies are necessary to evaluate the effects of IL-7 on immune reconstitution.

Interleukin 9

IL-9 protein sequence contains 144 residues with a signal peptide of 18 amino acids. The human IL-9 gene is a single copy gene and was mapped on chromosome 5, in the 5q31q35 region, which contains various growth factor and growth factor receptor genes such as IL-3, IL-4, IL-5, GM-CSF, and CSF-1 receptor (CSF-1R) (Renauld 2000).

So far, IL-9 expression seems to be mainly restricted to activated CD4$^+$CD45RO$^+$ T cells (Houssiau et al. 1995), HTLVI- infected T-cell leukemias (Kelleher et al. 1991), and Hodgkin's cell lines (Merz et al. 1991). Polyclonal T-cell stimulants induce a substantial IL-9 expression by T-cell-enriched lymphocyte populations, and more specifically, by CD4$^+$CD45RO$^+$ T cells. IL-9 expression appears in the late stages of T-cell activation, with a peak at 28 h. IL-2 was identified as a major

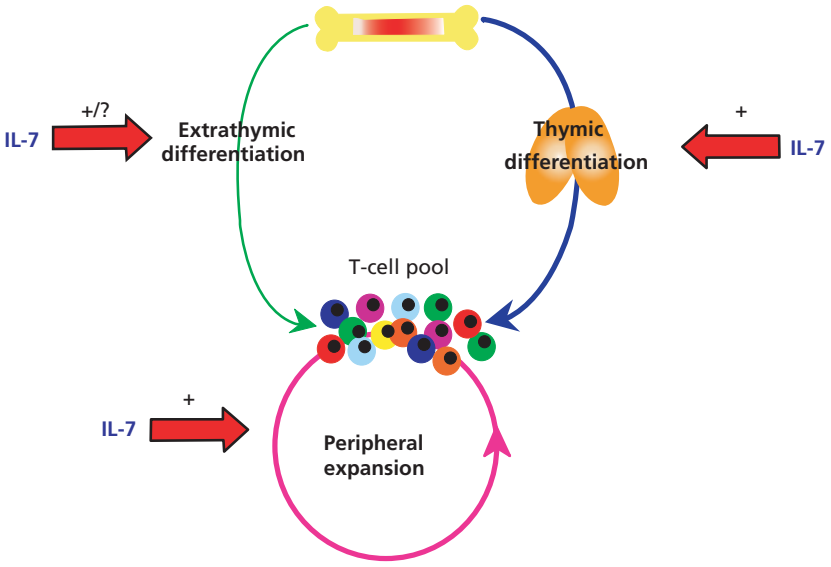

Figure 6 *Modulation of T-cell regenerative pathways by the interleukin IL-7. After T-cell depletion, regeneration of the peripheral T-cell pool can occur through multiple mechanisms. Thymic differentiation is the predominant pathway through which new T cells are generated if thymic capacity is sufficient. However, with diminished thymic function related to therapy-related toxicity, or age-related decline, the peripheral expansion of remaining mature T cells can substantially regenerate the T-cell pool. Extrathymic differentiation from bone marrow progenitors is a relatively minor pathway through which new T cells develop. IL-7 can profoundly increase thymic differentiation, peripheral expansion, and potentially extrathymic differentiation pathways to T-cell regeneration. (Redrawn from Fry and Mackall 2002, with permission.)*

mediator of IL-9 expression, because anti-TAC antibodies completely block this process.

Several studies indicate that IL-9 not only is involved in the late growth of T cells, but also induces the proliferation and differentiation of mast cells. Other potential biological targets for IL-9 include B lymphocytes, eosinophils, and hemopoietic progenitors. IL-9 might play an important role in the immune response against intestinal parasites such as helminths, probably by contributing to the development of mucosal mast cell hyperplasia induced by worm infections. Resistance to *Trichuris muris* was found to correlate with the production of IL-5 and IL-9 in mesenteric lymph nodes. The existence of an IL-9-mediated autocrine loop has been suggested for Hodgkin's disease. In addition, both genetic and experimental evidence points to the implication of IL-9 in the pathogenesis of asthma (Figure 7).
The potential activity of IL-9 in autoimmunity models is illustrated by preliminary data obtained in nonobese diabetic (NOD) mice (Renauld 2000).

Interleukin 15

IL-15 is a 15-kDa glycoprotein whose mature form consists of 114 amino acids. The IL-15 gene was mapped to chromosome 4q31. The classic long (48 amino acids) signal peptide associated with all secreted IL-15 is encoded by a 1.6 kbp cDNA (Waldmann and Tagaya 2000).

There is widespread constitutive expression of IL-15 mRNA in a variety of tissues (Waldmann and Tagaya 2000). IL-15 stimulates the proliferation of activated $CD4^+$ and $CD8^+$ T cells and dendritic epidermal T cells. IL-15 does not have any effect on resting B cells, but it induces proliferation and immunoglobulin synthesis by B cells costimulated with phorbol myristate acetate or an immobilized anti-IgM antibody. However, the most critical function of IL-15 is a pivotal role in the development, survival, and activation of NK cells (Figure 8).
IL-15 also has unique functions on nonlymphoid cells, including mast cells and muscle, brain, and microglial cells. The action of IL-15 on T cells, B cells, and NK cells can be blocked by selective antibodies to the IL-2/15Rβ chain. IL-15 acting through the IL-2/15Rβ and γc receptors leads to the induction of the expression of IL-2Rα by T lymphocytes.

Failure to produce IL-15 has not been demonstrated in disease states, although presumably it would be associated with the absence of NK cell development. Abnormalities involving increased IL-15 expression have been reported in inflammatory autoimmune diseases. IL-15 may precede tumor necrosis factor-α (TNF-α) in the cytokine cascade and suggest a role for IL-15 in development of rheumatoid arthritis, as well as in other inflammatory diseases, including active ulcerative colitis, Crohn's disease, type C chronic liver disease, sarcoidosis, T-cell-mediated alveolitis, and multiple sclerosis. Furthermore, the observation that IL-15 stimulates mast cell proliferation suggests a potential role for this cytokine in mastocytosis. IL-15 was shown to help correct impaired proliferative responses of $CD4^+$ lymphocytes studied ex vivo from HIV-infected individuals. Thus, as IL-15 is associated with less severe capillary leak syndrome than

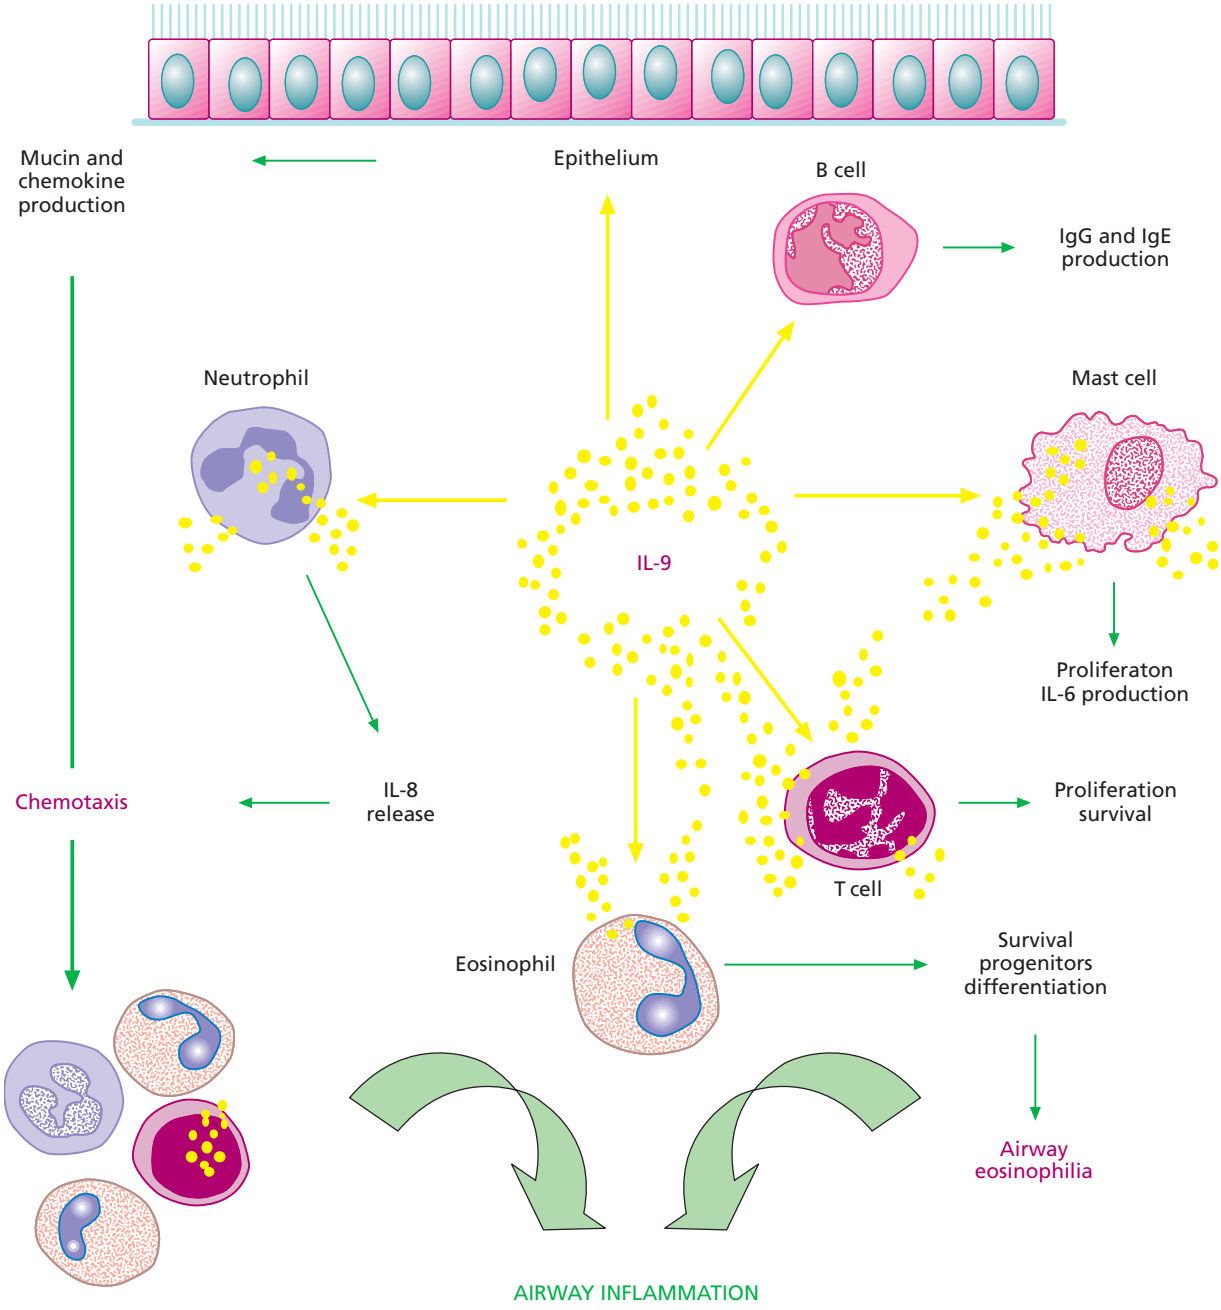

Figure 7 *Role of the interleukin IL-9 in pathophysiological manifestations of allergic inflammation and bronchial asthma. IL-9, a T-helper 2 (Th2) cytokine, has a pleiotropic activity on inflammatory and structural cells associated with asthma, such as mast cells, T cells, eosinophils, and epithelial cells. Within the lung, IL-9 is mainly produced by T cells and, to a lesser extent, by granulocytes. The effect of IL-9 leads to various immunological processes, including eosinophil survival, chemokines, and mucus production. These pathways may provide a potential mechanism to explain airway inflammation. (Redrawn from Soussi-Gonoussi et al. 2001, with permission.)*

the IL-2 molecule, it could provide an alternate therapeutic option to IL-2 in the treatment of patients with select tumors or AIDS (Waldmann and Tagaya 2000).

Interleukin 21

IL-21 is a four-helix-bundle cytokine with 131 amino acids that has significant sequence with homology to IL-2, IL-4, and IL-15. The IL-21R has highest homology to the IL-2Rβ chain and the IL-4Rα chain. On ligand binding, IL-21R has been reported to associate with the common γ chain, a property that it shares with receptors for IL-2, IL-4, IL-7, IL-9, and IL-15. The main source for IL-21 seems to be activated T lymphocytes. IL-21 apparently influences the functions of B cells, T cells, and NK cells (Parish-Novak et al. 2000). Moreover,

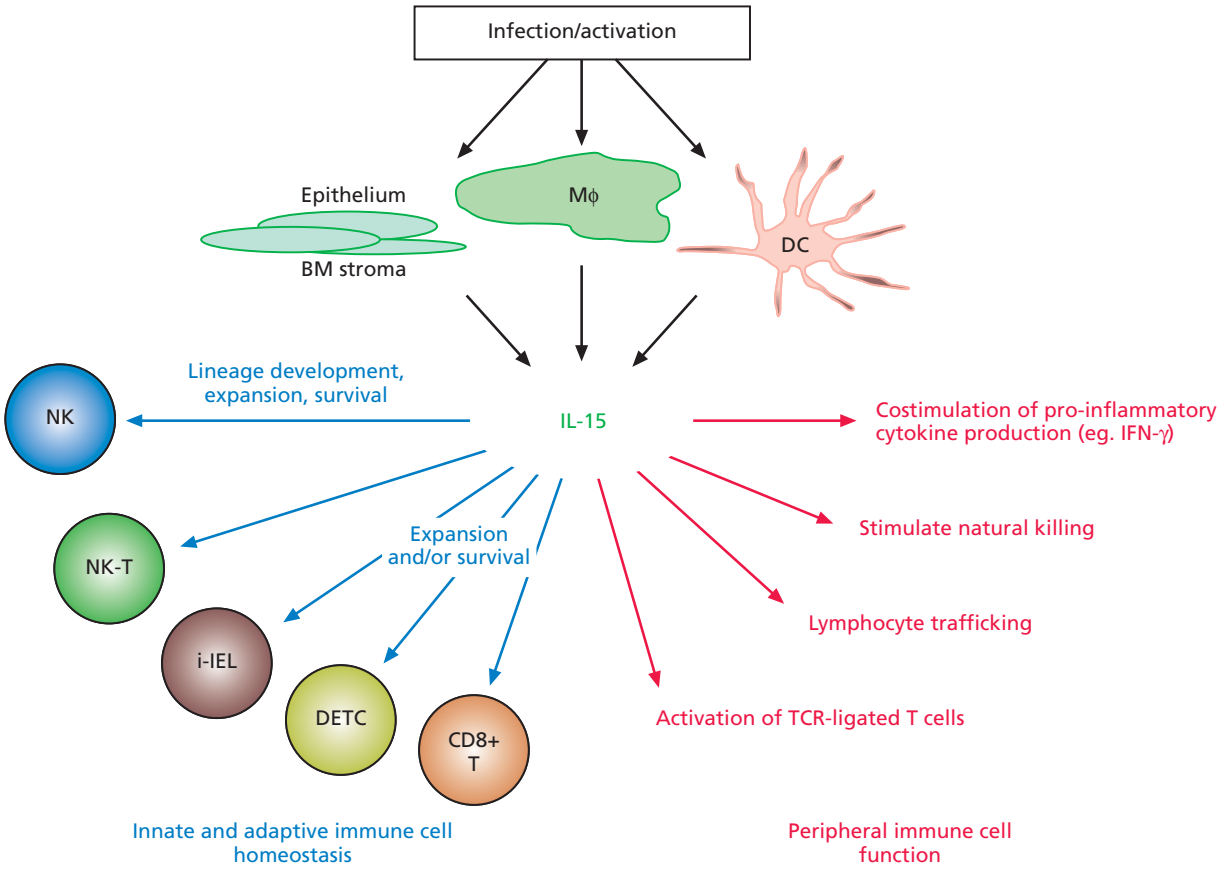

Figure 8 *Role of interleukin IL-15 in natural killer (NK) cell development, lymphocytes homeostasis, and peripheral immune functions. Multiple cell types elaborate IL-15, including activated monocytes/macrophages, dendritic cells, and epithelium, as well as constitutive production by bone marrow stromal cells. IL-15 has a critical role in the development of NK lineage, as well as in its survival, expansion, and function. Other innate lymphocyte (NK-T, CD8αα intestinal intraepithelial lymphocytes, TCRγδ DETCs) and memory phenotype CD8$^+$ T cells depend on IL-15 for survival or expansion. DETC, dendritic epidermal T-cells; IFN, interferon; Mϕ, macrophage; TCR, T-cell receptor. (Redrawn from Fehniger and Caligiuri 2001, with permission.)*

IL-21 has recently been shown to exert a proliferative effect on human myeloma cells and to inhibit the apoptosis of the IL-6-dependent human myeloma cell lines with a potency close to that of IL-6 (Brenne et al. 2002).

Interleukin 27

IL-27 is a new heterodimeric cytokine composed of EB13 (an IL-12 p40-related protein) and p28 (a new IL-12 p35-related polypeptide). It represents an early product of activated antigen-presenting cells (APC) and induces the proliferation of naïve, but not memory, CD4$^+$ T cells. It also synergizes with IL-12 for the development of Th1 cells via the receptor TCCR/WSX-1 (Pflanz et al. 2002).

PROINFLAMMATORY CYTOKINES

Interleukin 1

There are two distinct species of IL-1, which have been named as IL-1α and IL-1β, respectively. IL-1α is initially synthesized as a (31-kDa) precursor molecule without a signal peptide, mature IL-1α being a 17.5-kDa molecule. Calpain, a calcium-activated cysteine protease, is responsible for the cleavage of the IL-1α precursor (Dinarello 2000b). IL-1β is initially synthesized as a precursor molecule (31 kDa) without a signal peptide. Mature IL-1β is a 17-kDa molecule. The IL-1β-converting enzyme (ICE) is primarily responsible for cleavage of the precursor intracellularly, but other proteases can also process the IL-1β precursor into an active cytokine (Dinarello 2000a, 2000b).

Blood monocytes and tissue macrophages are the main sources of IL-1α and IL-1β. However, unlike IL-1β, IL-1α is found constitutively expressed also in keratinocytes and other epithelial cells. Virtually all microbes and microbial products induce the production of both IL-1α and IL-1β. The main differences between the two cytokines are summarized in Table 4.

IL-1 induces neutrophilia and the production of acute phase proteins (APP), and the injection of modest doses of IL-1 into mice results in fever, anorexia, and the production of circulating IL-6. The most dramatic

Table 4 *A comparison of interleukins IL-1α and IL-1β*

IL-1α	IL-1β
Pro-IL-1α is active	Pro-IL-1β is inactive
Active membrane form is IL-1α	Membrane IL-1β not observed
Mature IL-1α does not circulate	Mature IL-1β circulates
Nuclear localization	No nuclear localization
Intracellular role for pro-IL-1α	No intracellular role for pro-IL-1β
Neutralizing autoantibodies	Non-neutralizing autoantibodies
Calpain cleavage of pro-IL-1α	ICE and PR-3 cleavage of pro-IL-1β
No disease link with calpain expression	Disease link with ICE expression
No correlation	Correlation with bone resorption
IL-1α knock-out mice normal	IL-1β knock-out mice resistant to disease
Anti-IL-1α ineffective in CIA	Anti-IL-1β effective in CIA
IL-1α expression in AML absent	IL-1β expression in AML present
No data	ICE inhibition→reduced brain ischemia
No data	ICE inhibition→reduced AML proliferation
No data	ICE antisense→reduced AML proliferation

AML, acute myeloid leukemia; CIA, collagen-induced arthritis; ICE, IL-1β-converting enzyme; PR-3, a compound used for cleavage.
From Dinarello (2000b).

responses to the pharmacological effects of IL-1 are observed in humans. The role of IL-1 in human disease states is best revealed by the response of humans to parenterally administered IL-1. Chills and fever are observed in nearly all patients. The febrile response increases in magnitude with increasing dose, and chills and fever can be abated with indometacin (indomethacin) treatment. IL-1 is also a potent immunoadjuvant for several tumors. IL-1 has been administered to patients during receipt of ABMT. The treatment with IL-1 of ABM or SC transfer resulted in an earlier recovery of thrombocytopenia compared with controls (Dinarello 2000b).

Interleukin 6

Human IL-6 is a protein of 186 amino acids glycosylated at positions 73 and 172. It is synthesized as a precursor protein of 212 amino acids. At least five different molecular forms of IL-6 with molecular masses from 21 to 28 kDa are expressed in monocytes. The IL-6 gene has a length of approximately 5 kb and maps to human chromosome 7p21 between the markers D7S135 and D7S370 (Matsuda and Hirano 2000).

IL-6 is produced by a variety of cell types. The main sources are macrophages, fibroblasts, and endothelial cells, but also T and B cells. The IL-6 receptor consists of two subunits: the α chain (IL-6R), an 80-kDa transmembrane glycoprotein that binds IL-6 with low affinity, and the β chain (gp130), a 130-kDa transmembrane glycoprotein that binds to the IL-6–IL-6R heterodimer to form the high-affinity signal transducing complex (Matsuda and Hirano 2000).

IL-6 induces immunoglobulin production by normal activated or EBV-transformed or leukemic B cells. IL-6 is involved in T-cell activation, growth, and differentiation. IL-6 synergizes with IL-3 to induce the proliferation of murine pluripotent hemopoietic progenitors in vitro. Human megakaryocytes were demonstrated to express IL-6 receptor and produce IL-6, suggesting that IL-6 regulates the terminal maturation of megakaryocytes in an autocrine manner. However, the most important function of IL-6 is to induce the biosynthesis by hepatocytes of APPs, such as fibrinogen, α1-antichymotrypsin, haptoglobulin, serum amyloid A, and C-reactive protein (CRP) (Geiger et al. 1988). As a result of the ability of IL-6 to act as a growth factor for plasmacytoma, myeloma, and hybridoma cells, different inhibitors of IL-6, such as anti-IL-6 monoclonal antibody and mutated IL-6, might be used to treat patients with multiple myeloma, Castleman's disease, and rheumatoid arthritis (Hirano 1998).

TNF-α

TNF-α under denaturing conditions is about 17 kDa. Under native conditions, however, TNF-α is a trimer with an approximate molecular mass of 50 kDa. The TNF-α gene is localized on human chromosome 6 in a region between p23 and q12 (p21.1 and p21.3) (Aggarwal et al. 2000).

Although first isolated from a macrophage-like cell line, it is now clear that TNF is produced by a wide variety of different cell types, including macrophages and monocytes, T, B, and NK cells, astrocytes, fibroblasts, basophils, mast cells, Kupffer cells, smooth muscle cells, and epidermal cells, as well as neoplastic cells from breast tumor, ovarian tumor, prostate tumor, pancreatic cancer, glioblastoma, melanoma, and leukemia. However, monocytes/macrophages are prob-

ably the major sources of TNF in most conditions (Aggarwal and Vilcek 1992).

Tumor necrosis factor binds to two different receptors referred to as p60 (also called p55, or type I or CD120a) and p80 (also called p75, or type II or CD120b) based on their molecular weight. These two receptors are homologous in their extracellular domains, but distinct in their intracellular domains. The p60 receptor is expressed on all cell types, whereas the p80 form is expressed chiefly on cells of the hemopoietic and immune system, as well as on endothelial cells. The binding of TNF to its receptor can be displaced by lymphotoxin, suggesting that they have a common receptor.

The true normal physiological role of TNF in vivo is unclear. TNF is an inflammatory cytokine, because of its chemotactic activity on monocytes and neutrophils. Moreover, stimulation with TNF induces phagocytosis, and adherence of these cells to endothelial cells, as well as generation of free radicals of oxygen, superoxide anion, and hydrogen peroxide. Therefore, it is believed that TNF is important for protection against bacterial, fungal, parasitic, and perhaps even viral infections and other stressful stimuli. Besides hemorrhagic necrosis, whether TNF is able to block tumorigenesis and metastasis in vivo is still not fully understood (Lejeune et al. 1998). Administration of TNF to various animals leads to hemorrhage, necrosis, local inflammation, shock, and death. Prolonged exposure to TNF causes anorexia, loss of body weight, dehydration, and loss of body proteins and lipids. This condition, called cachexia, may occur during chronic parasitic, bacterial, and viral infections. The symptoms also appear in cancer patients. The mediator involved in this process was named cachectin, later recognized to be the same as TNF. In severe diseases such as AIDS, the TNF level is significantly increased when the signs and symptoms of cachexia develop. Stimulation of cultured human endothelial cells with TNF induces procoagulant activity. TNF-induced endothelial cell activation leads to the structural reorganization of the endothelium, resulting in vascular leakiness that is partly caused by its capacity to upregulate vascular endothelial growth factor (VEGF). The main activities of TNF-α are summarized in Figure 9. TNF is considered as a major mediator of septic shock, because it is overproduced during sepsis and administration of high doses of TNF-inducing LPS causes shock and tissue injury that are identical to sepsis (Aggarwal et al. 2000).

Lymphotoxins

Lymphotoxin (LT) was initially discovered as a secreted cytotoxic/cytostatic factor produced by activated lymphocytes. It was then recognized as a member of a large superfamily (Table 5). A distinct cell surface form of LT was defined as a heterotrimer made up of a subunit of LT with a dimer of a 33-kDa protein, designated LTβ, the third member of the family. The soluble LT is known as LTα, which was previously called TNF-β. The cell surface form of LT is formed by two subunits, LTα and LTβ. Two distinct heterotrimers are formed, LTαβ2 (major form) and LTα2β1. LTα is TNF splicing factor (SF)1 and LTβ is TNFSF3. LTα is a secreted glycoprotein of 171 amino acids with a secondary structure of antiparallel sandwich structure which assembles into a relatively compact trimer, a feature common to all members of the TNF superfamily. LTβ is a type II transmembrane glycoprotein (N-terminal cytosolic tail), which lacks a signal cleavage sequence and is retained in the membrane. LTβ is biologically active as a heterotrimer with LTα. The LTαβ ligand remains anchored to the cell membrane and, as such, acts in a localized fashion that requires cell-to-cell contact. By contrast, LTα lacks a retained transmembrane domain and is exclusively secreted as a homotrimer. TNF, LTα, and LTβ form a contiguous cytokine locus that resides on chromosome 6p21.3 (chromosome 17 in mouse) within the major histocompatibility gene complex (MHC). The LTα, LTβ, and TNF genes show similar intron and exon organization (Wallach et al. 1999), which is largely conserved for all members of the TNF superfamily.

The main sources of LTα and LTβ are activated T and B lymphocytes, but LTs are also produced by NK and lymphokine-activated killer (LAK) cells in response to IL-2. LTα binds to the receptors TNFRI and TNFRII with high affinity, and to HVEM with low affinity; LTα2β1 binds to the LTβR, whereas the LTα2β1 complex binds LTβ R weakly (25 nmol/l), but TNFRI and TNFRII with high affinity (Ware et al. 1998).

The in vitro biological responses to LTα and LTβ are very similar. However, based on dose–response curves, LTα is typically less potent compared with TNF in inducing most functions. LTα behaves as a partial agonist of TNF in some assays, such as induction of MHC molecules, intercellular adhesion molecule 1 (ICAM-1), and other types of markers of inflammatory reactions. LTα1β2 displays even weaker potency for induction of proinflammatory markers on various cell types, including endothelial cells. LTs play a role in the initiation of inflammation, which presumably contributes to the protection against microbes. LTα can also induce expression of adhesion molecules and chemokines, whereas LTαβ does not appear to be able to induce adhesion molecules, but can induce chemokines. LTα and LTβ may play normal roles in tumor immunity. LTα induces apoptosis (programmed cell death) in several tumor lines in vitro and LTα1β2 induces killing of a more limited array of tumor cells. This effect is the result of the action of a distinct types of receptor; LTα uses TNFRI, a death domain proapoptotic signaling receptor that directly activates the caspase pathway,

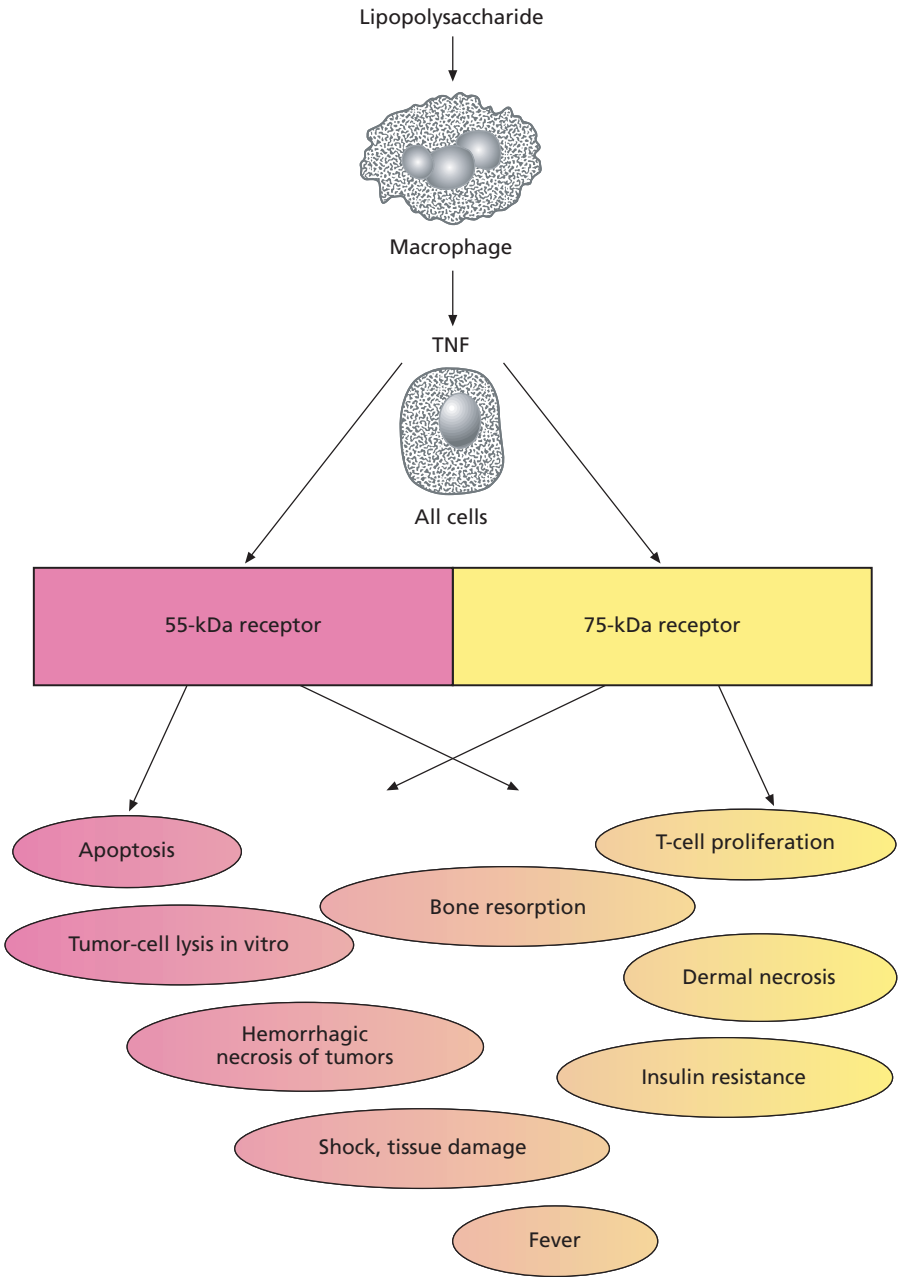

Figure 9 *Range of actions of tumor necrosis factor α (TNF-α). In response to inflammatory stimuli, such as lipopolysaccharide (LPS), macrophages produce TNF-α. TNF-α binds to receptors present on virtually all cells throughout the body, causing a variety of reactions. (Redrawn from Bazzoni and Beutler 1996, with permission.)*

whereas LTα1β2 uses the LTβR, a TRAF-binding receptor and a potent activator of apoptotic inhibitory pathways, such as NF-κB transcription factor (Ware et al. 1998). LT gene-deficient mice lack most lymph nodes, do not have Peyer's patches, and have disorganized spleens (Alimzhanov et al. 1997). LTs are elevated in several human diseases, including multiple sclerosis, juvenile rheumatoid arthritis, juvenile spondylarthropathy, and Crohn's disease, suggesting an important role of LTs in these disorders.

Interferon-γ

In its biologically active form, IFN-γ is a 34-kDa homodimer stabilized by noncovalent forces. The IFN-γ gene maps close to the D12S335 and D12S313 microsatellites and shows physical linkage with the *MDM2* oncogene on chromosome band 12q15 (Billiau and Vandenbroeck 2000).

Interferon-γ is a typical lymphokine, being produced almost exclusively by NK cells and certain subpopula-

tions of T cells. Both $CD4^+$ and $CD8^+$ lymphocytes can produce IFN-γ, but only Th1 cells produce IFN-γ following appropriate stimulation, whereas Th2 cells do not. IFN-γ acts on cells by inducing increased expression of several genes, the spectrum of which varies depending on the cell type concerned and the presence of other cytokines, some of which (e.g. IFN-γ) synergize with IFN-γ, whereas others (e.g. IL-4) antagonize its activities. Receptors for IFN-γ occur on virtually all cells of the body, so that many organs and systems undergo the action of IFN-γ (Billiau and Vandenbroeck 2000).

Interferon-γ regulates cellular activities responsible for inflammation, in particular the activation state of macrophages and endothelial cells. It also regulates the antigen-specific immune response by affecting both APCs and antigen-recognizing lymphocytes. IFN-γ has an important role in the generation of NO. Another important function of IFN-γ is the induction of MHC class II antigens on many, although not all, cell types, thus enhancing or inducing the ability of these cells to present foreign antigens. IFN-γ can also increase the expression of MHCI antigen. It is recognized as the most important cytokine converting macrophages from a 'resting' to an 'activated' state (macrophage activating factor (MAF)). IFN-γ and IL-4 antagonize each other in a variety of systems, and it has been established that antibody responses in fact depend on the balance between two categories of cytokines, IFN-γ and IL-2 produced by Th1 cells and IL-4, IL-5, IL-6, and IL-10 produced by Th2 cells. In this context, IFN-γ suppresses IgG1 and IgE and stimulates IgG2a antibody formation. Thus IFN-γ is not only important in the initial phase (aspecific inflammatory and antigen presenting) and in the middle phase (expansion and differentiation of antigen-reactive lymphocyte clones), but also in the end phase (sustained or final inflammation) of immune reactions. Defects in the IFN-γ mechanism are associated with severe impairment of resistance to infections caused by viruses and certain bacteria, in particular those normally killed by activated macrophages. Massive production of IFN-γ, occurring as part of so-called acute cytokine release syndromes, is often associated with severe systemic manifestations, such as generalized bleeding and lethal shock. IFN-γ has the potential to protect the host against virus infection, not only because of its regulatory activity on immunocytes, but also by virtue of its direct antiviral effect on most cell types. IFN-γ contributes to protection against tumors, as shown by studies in which the rejection of some immunogenic autologous or isologous tumors was abrogated by administration of neutralizing anti-IFN-γ antibodies. In children suffering from exceptional susceptibility to mycobacterial infections, inherited deficiencies in the IFN-γ receptor system have recently been described (Billiau and Vandenbroeck 2000).

Interleukin-12

IL-12 is a 70-kDa heterodimer composed of two disulfide-linked chains of 35 kDa (p35) and 40 kDa (p40). The genes encoding the two heterologous chains of IL-12 are located on different chromosomes. In humans, p40 is located in the 5q31–q33 region, whereas p35 has been mapped to 3p12–p13.2. Secretion of the biologically active IL-12 heterodimer (p70) is regulated at the level of p40 chain transcription. The p40 gene is highly inducible and expressed only in IL-12-secreting cells, whereas the p35 gene is expressed ubiquitously (Esche et al. 2000).

IL-12 was initially recognized as an inducer of IFN-γ synthesis by resting human peripheral blood mononuclear cells (PBMC) in vitro and as being capable of synergizing with IL-2 to increase cytotoxic lymphocyte responses. IL-12 also represents a growth factor for activated $CD4^+$ T cells, $CD8^+$ T cells, and NK cells, and most importantly it promotes Th1-specific immune responses (Manetti et al. 1994) (Figure 10). Thus, IL-12 enhances host defenses against organisms that are controlled by cells mediating the delayed hypersensitivity response of T cells.

Dendritic cells are the most powerful producer of IL-12 when stimulated with CD154 (CD40L) or IL-12. Epidermal Langerhans' cells express IL-12 p40 mRNA,

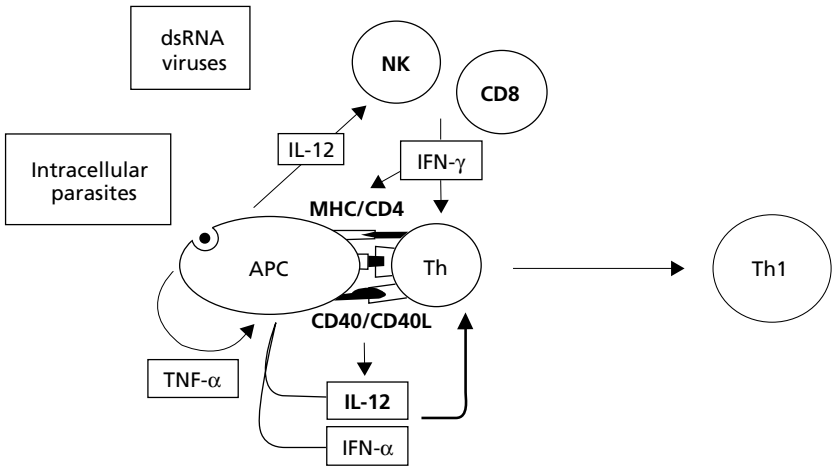

Figure 10 *Role of IL-12 in the differentiation of naive T-helper (Th) cells into Th1 effectors. Intracellular bacteria and some viruses strongly activate dendritic cells and macrophages to produce interferon α (IFN-α) and IL-12, as well as natural killer (NK cells) to produce IFN-γ. Under these microenvironmental conditions and in the absence of IL-4, naïve Th cells responsible for the subsequent specific immune response differentiate into Th1 effectors. (Reproduced from Romagnani 1998, with permission.)*

as well as p40 and functional p70 protein. Stimulated macrophages produce both p40 and p70. Although monomeric p40 is typically secreted in large excess over the p70 heterodimer, only the latter is biologically active. In humans, the homodimer binds with a much lower affinity than the heterodimer and therefore acts as an antagonist only at much higher concentration. IL-12-induced production of large amounts of IFN-γ from resting and activated T and NK cells requires the presence of low levels of both TNF-α and IL-1. IL-12 is also capable of inducing its own inhibitor IL-10, a negative-feedback mechanism that limits ongoing T-cell activation. IL-12 promotes the generation and potentiates the activity of cytotoxic T lymphocytes (CTL) and LAK cells (Trinchieri 1998).

This array of activities suggests clinical potential for IL-12 as an anti-infective and antitumor agent. The lack of IL-12R expression indeed results in a human immunodeficiency characterized by strong reduction in resistance to infections caused by intracellular bacteria. The attempt to administrate IL-12 in patients with cancer has been hampered by adverse events that are mostly IFN-γ dependent and include fever, chills, fatigue, headache, nausea, vomiting, cough, myalgia, dizziness, insomnia, anemia, neutropenia, lymphocytopenia, thrombocytopenia, hyperglycemia, liver function test abnormalities, rhinitis, stomatitis, and colitis. Three deaths have also been reported in renal carcinoma patients receiving IL-12, but prior exposure to IL-12 has been shown to protect against IL-12 toxicity (Leonard et al. 1997).

Interleukin 16

IL-16 is a 55-kDa protein which appears as a single 17-kDa band on sodium dodecylsulfate (SDS) gel electrophoresis, prompting the hypothesis of a monomeric polypeptide autoaggregated into tetramers. The IL-16 gen is located in chromosome 15q26.1 (Center et al. 2000).

IL-16 is synthesized by a variety of cell types although it was first identified as a $CD8^+$ lymphocyte cell product. $CD8^+$ T cells release IL-16 in response to stimulation by mitogens, antigens, or vasoactive amines such as histamine and serotonin (Laberge et al. 1996). For histamine, H_2-type receptors are required based on inhibition of secretion by H_2-, but not H_1-, receptor antagonists. Histamine has no effect on the secretion of IL-16 from $CD4^+$ T cells. Serotonin has similar effects on $CD8^+$ T cells via S2 receptors, but no effect on $CD4^+$ T cells.

IL-16 was initially described as a chemoattractant with specificity for $CD4^+$ T cells. It was later observed that IL-16 is also a potent chemoattractant for all peripheral immune cells expressing CD4, including $CD4^+$ monocytes, eosinophils, and dendritic cells. The role of IL-16 in vivo remains to be elucidated; however, one possibility is that it contributes at least in part to antigen-independent, nonclonal recruitment and priming of $CD4^+$ cells in inflammatory processes, whereas the same cells become unresponsive to specific antigen stimulation. This condition may result in the increase of the number of viable cells recruited to an inflammatory site by reducing the susceptibility of those cells to antigen-induced cell death (AICD). As a result of these activities, IL-16 has to be considered as a proinflammatory cytokine. It may play an important role in the pathogenesis of diseases characterized by $CD4^+$ cellular infiltration, such as bronchial asthma and granulomatous diseases (Center et al. 2000).

Interleukin 17 family

IL-17 is secreted, after cleavage of a signal peptide of 23 amino acids, as a glycoprotein homodimer of

155 amino acids with an M_r ranging from 22 to 15 kDa. IL-17 gene has been mapped to chromosome 2 (2q31).

IL-17 appears to be mostly expressed by activated $CD4^+$ T cells, in particular by CD4/$^+$CD45RO 'memory' T cells. All T-cell activation signals upregulate IL-17 gene transcription. Analysis of T-cell clones suggests that both Th1 and Th2 $CD4^+$ subsets can express IL-17 at comparable levels. The IL-17R is ubiquitously expressed.

IL-17 was found to exert biological effects on cells of hemopoietic origin and stromal cells, to induce the secretion of IL-6 by skin and lung fibroblasts and by normal and rheumatoid synoviocytes. It also stimulates the production of IL-8, PGE_2, G-CSF, and leukemia inhibitory factor (LIF) by rheumatoid synoviocytes, upregulates the expression of ICAM-1 by foreskin fibroblasts, stimulates the production of NO by normal and osteoarthritic human articular chondrocytes, and increases their production of IL-1, IL-6, stromelysin, the inducible NO synthase (iNOS), and cyclooxygenase 2 (COX-2). IL-17 stimulates the production by endothelial and epithelial cells of several chemokines. IL-17 increases the secretion of G-CSF by human synoviocytes and by murine fibroblasts, leading fibroblasts to support the growth and differentiation of $CD34^+$ hemopoietic progenitors into mature neutrophils. IL-17 cooperates with TNF-α, IFN-γ, and IL-1 to induce the secretion of IL-6 by rheumatoid synoviocytes and with IFN-γ to enhance the production of IL-6 and IL-8 and to upregulate the expression of ICAM-1 and HLA-DR by human keratinocytes (Yao et al. 1995a, b). Thus, IL-17 mainly exhibits proinflammatory and hemopoietic activities, which appear to play an upstream role in T-cell-triggered inflammation and hemopoiesis, by stimulating stromal cells to secrete other cytokines and growth factors. The hemopoietic effect of IL-17, and in particular its ability to trigger indirectly an acute neutrophilia, might have therapeutic applications in the context of immunosuppression, i.e. after bone marrow transplantation. On the other side, IL-17 might represent a target for therapeutic inhibition in T-cell-dependent autoimmune diseases, chronic inflammatory conditions of the lung, skin, and intestinal tract, organ graft rejection, and some cancers (Lebecque et al. 2000).

More recently, three IL-17-associated molecules have been described, which have been called IL-17B, IL-17C, and IL-17F. Although also these new members can promote inflammation and hemopoiesis, some of the activities of IL-17B and -C are distinct from those described for IL-17, e.g. IL-17B and -C do not bind to IL-17R and only promote the expression of TNF-α and IL-1β, but not of IL-6, IL-8, and G-CSF. IL-17F-induced substantial increases in the mRNA for inflammatory cytokines and chemokines, including IL-6, IFN-γ, CXCL10, and CXCL9 (Li et al. 2000; Shi et al. 2000; Starnes et al. 2001).

Interleukin 18

IL-18 is a protein consisting of 193 amino acids showing homology with IL-1. IL-18 is processed by a protease-like ICE. Moreover, the receptor for IL-18 was shown to be a member of the IL-1 receptor family. The IL-18 gene is located on chromosome 11q22.2.3, closely linked to the dopamine receptor D2 (DRD2) locus, whereas the IL-18R gene maps to chromosome 2q11, on which human IL-1 family members and IL-1R type I are located (Okamura et al. 1995).

A wide range of cell types, including mononuclear cells, keratinocytes, osteoblastic cells, intestine epithelial cells, dendritic cells, chondrocytes, and neuroblastomas, express IL-18. However, IL-18 is mainly produced by activated macrophages or dendritic cells.

IL-18 was originally discovered as an IFN-γ-inducing factor for $CD4^+$ T cells. IL-18 by itself, as IL-12, induces only small amounts of this cytokine. However, combined stimulation of IL-18 and IL-12 induces remarkably higher production of IFN-γ. The underlying mechanism for this strong synergism is that IL-12 induces the IL-18R on $CD4^+$ T cells. $CD8^+$ T cells are also an important source of IFN-γ, and the same synergistic mechanism with IL-12 seems to be operating on $CD8^+$ T cells, although IL-18 also directly activates the cytotoxicity of $CD8^+$ T cells (Biet et al. 2002). When IL-18 was discovered, it was considered to be another factor that could differentiate naïve Th cells into Th1 effectors, such as IL-12. More recent studies have revealed that IL-18 itself has no ability to drive the differentiation of Th1 cells, but strongly induces them to express their functions and induce synthesis of IFN-γ or Fas ligand. However, surprisingly, it was recently found that IL-18, as IFN-γ, also enhances production of the Th2 cytokine IL-13 in T and NK cells. These findings suggest that IL-18 may be involved in the amplification, as well as the regulation, of Th1 responses through the induction of Th2 cytokine production. As with its actions on T cells, IL-18 alone, as well as IL-12 alone, induces NK cells to produce only a little IFN-γ, but again IL-18 and IL-12 synergize in the induction of IFN-γ by NK cells. The main targets of IL-18 and its mechanisms of action are summarized in Figure 11.

Since IL-18 induces IFN-γ production, it is obvious that this cytokine is involved in the defense mechanism against intracellular parasites, such as mycobacteria and *Listeria* spp. Recently, IL-18 was shown to contribute also to host defenses against *Salmonella typhimurium*, *Yersinia enterocolitica*, *Cryptococcus neoformans*, and some viruses, such as Epstein–Barr virus, influenza A virus, Sendai virus, herpes simplex virus, vaccinia, and encephalomyocarditis. Although IL-18 exhibits antitumor activity against several types of cells, the mechanism and mediating factors seem to be different for each type of tumor cell. Tumors transfected with

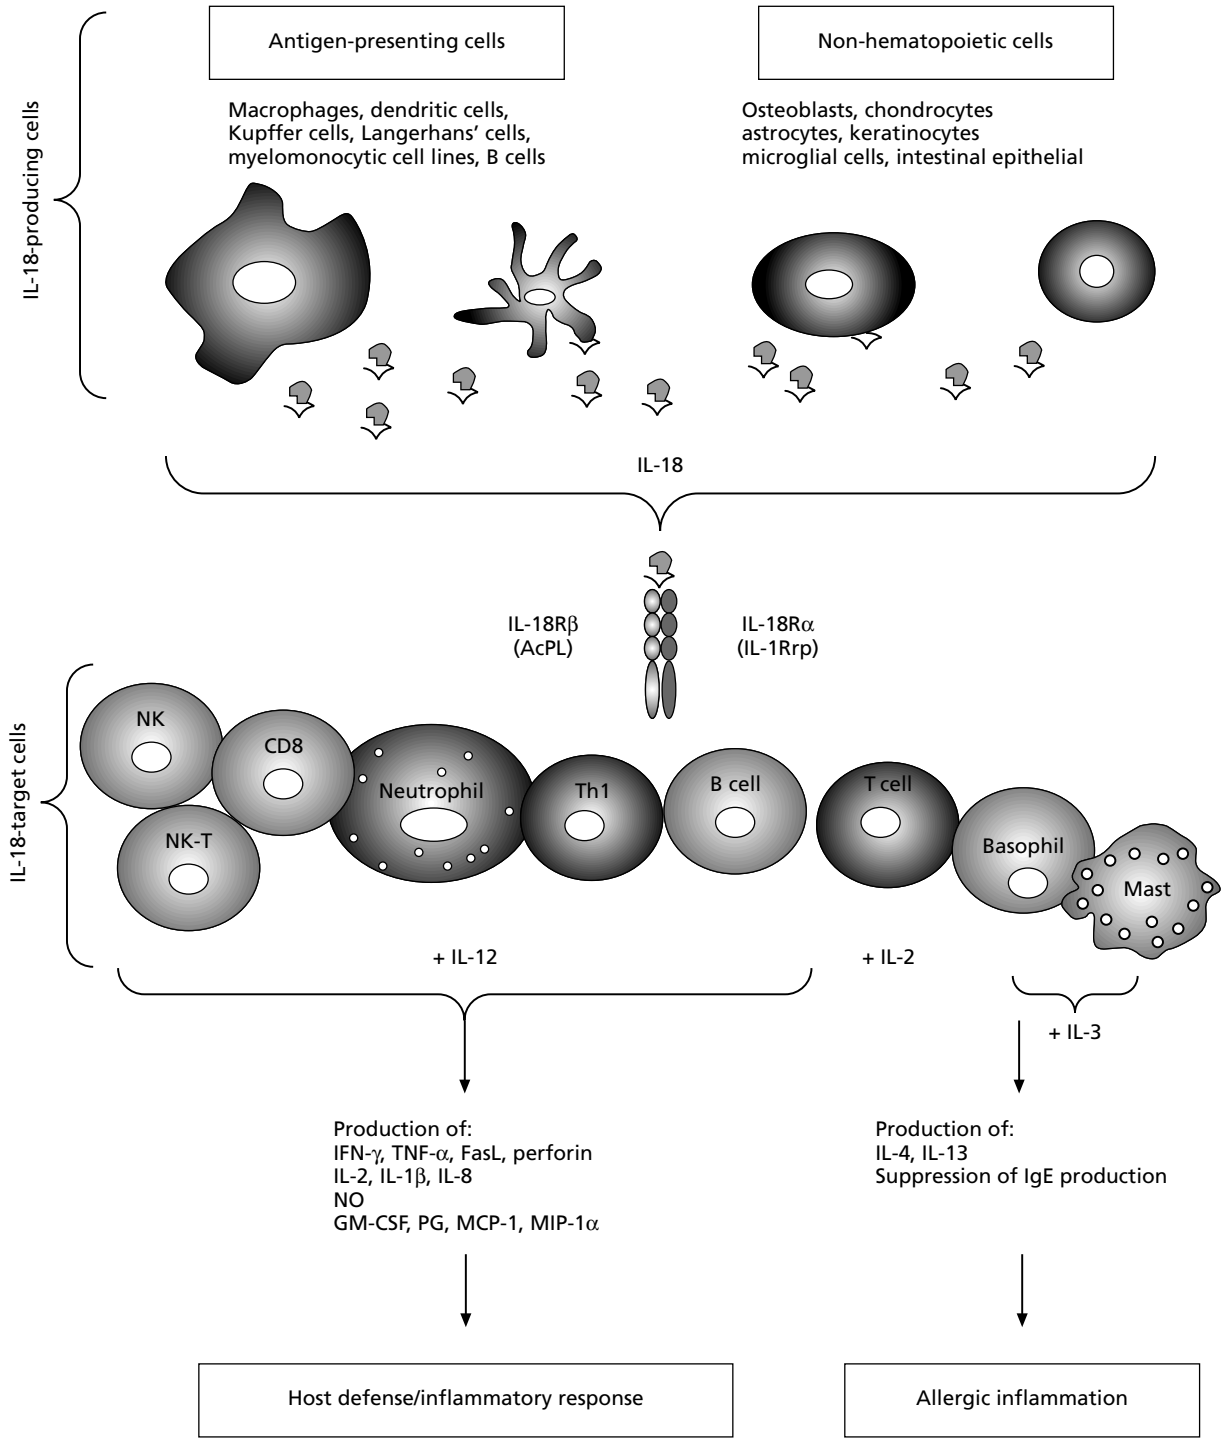

Figure 11 *Cellular sources and the targets of interleukin IL-18. Both antigen-presenting cells (APC) and nonhemopoietic cells produce IL-18. Synergy between IL-18 and IL-12 induce T-helper type 1 (Th1) differentiation increases the cytotoxic response of $CD8^+$ T cells, natural killer (NK) cells, and NK T cells and their production of interferon γ (IFN-γ), which results in the activation of macrophages. IL-18 has also the potential to induce Th2 cells in a IL-4-independent manner. In response to IL-18 and IL-3, mast cells and basophils produce large amounts of IL-4 and IL-13. Administration of a mixture of IL-12 and IL-18 inhibits IgE production. GM-CSF, granulocyte–macrophage colony-stimulating factor; MCP, monocytic chemotactic protein; MIP, macrophage inflammatory protein; TNF, tumor necrosis factor. (Redrawn from Biet et al. 2002, with permission.)*

IL-18 gene exhibited reduced tumorigenicity and exhibited immunoprotective effects against parental tumor cells in an IFN-γ-dependent manner. IL-18 is also involved in the pathogenesis of chronic inflammatory and autoimmune diseases, such as type 1 diabetes mellitus, experimental autoimmune encephalo-

myelitis, and chronic active hepatitis (Okamura et al. 2000).

Interleukin 23

The newly discovered cytokine IL-23 shares some in vivo functions with IL-12. This factor, which was termed p19, showed no biological activity itself, but combined with the p40 subunit of IL-12 to form a novel, biologically active compound. IL-23 binds to IL-12Rβ1, but fails to engage IL-12Rβ2 (Oppmann et al. 2000).

IL-23 is secreted by activated dendritic cells, induces the activation of the transcription factor Stat4 in stimulated T cells, a strong proliferation of memory T cells, and IFN-γ production by the same cells (Belladonna et al. 2002).

Interleukin 25

IL-25 is a recently discovered cytokine showing close homology with the other members of IL-17 family. IL-25 gene expression was detected following *Aspergillus* and *Nippostrongylus* infection in the lung and gut.

IL-25 induces responses similar to those mediated by Th2 cells, including IL-4, IL-5, IL-13, and eotaxin production, which is followed by eosinophil infiltrate and airway hyperreactivity (Hurst et al. 2002).

ANTI-INFLAMMATORY AND REGULATORY CYTOKINES

Interleukin receptor antagonist

IL-1R antagonist (IL-1Ra) is a member of the IL-1 family. Three forms of IL-1Ra have been described, two of them being expressed as intracellular proteins (icIL-1RaI and icIL-1RaII) and one being secreted (sIL-1Ra). The three forms of IL-1Ra result from the same gene. The function(s) of the intracellular forms of IL-1Ra are still elusive, whereas sIL-1Ra binds competitively to IL-1RI without inducing signal transduction and thus inhibits IL-1α and IL-1β actions. Mature sIL-1Ra (sIL-1Ra) is a protein of 152 amino acids which is generated by the cleavage of a hydrophobic signal sequence of 25 amino acids from a cytoplasmic precursor of 177 amino acids. The IL-1Ra gene is referred to as IL-1RN and has been mapped in the long arm of chromosome 2 at band q11 (Burger and Dayer 2000).

It is very likely that all cell types able to produce IL-1α and/or IL-1β also express sIL-1Ra or icIL-1Ra or both forms. However, most of the studies have reported the expression of sIL-1Ra in monocyte/macrophages, neutrophils, and fibroblasts and of icIL-1Ra in epithelial cells. In the brain, IL-1Ra is constitutively expressed by cell types other than those expressing IL-1, such as neurons of the paraventricular nucleus and supraoptic nucleus. The sIL-1Ra competitively binds the IL-1RI without inducing signal transduction. It is therefore likely that sIL-1Ra regulates (inhibits) cellular functions affected by IL-1α and/or IL-1β (Figure 12). The function(s) of intracellular forms of IL-1Ra are less obvious. One possibility may be that icIL-1Ra counteracts intracellular IL-1α activities and destabilizes and/or degrades mRNAs induced by IL-1α. More recently, it has been shown that resting and cytokine-stimulated human pulmonary epithelial cells release icIL-1RaI in the extracellular space, where it can antagonize cell surface IL-1R. Therefore, icIL-1Ra might be an epithelial store of IL-1Ra liable to immediate release. The role of IL-1Ra in normal physiology of healthy humans remains unclear. The serum levels of sIL-1Ra are elevated in many pathologies (Arend et al. 1998). Therefore, although IL-1Ra was inefficient in sepsis treatment, clinical trials are currently undertaken in inflammatory diseases.

Interleukin 10

IL-10 belongs to the family of long-chain cytokines. The mature IL-10 protein consists of 160 amino acids, Ser1 being the N-terminal residue. The predicted molecular weight of hIL-10 is 18 647 Da and it runs as a single species with an apparent molecular weight of 17 kDa in SDS–polyacrylamide gel electrophoresis (SDS-PAGE). Biologically active IL-10 is a homodimer. IL-10 is located on chromosome 1q. The human IL-10 gene spans 4.7 kb and consists of five exons separated by four introns.

IL-10 is expressed by naïve and memory T cells derived from either peripheral blood or cord blood, from T-cell clones belonging to Th1, Th2, and from T-regulatory 1 (Tr1) subsets, NK cells, and B cells derived from peripheral blood, tonsils, or spleen. A viral homolog of IL-10 has been found in the EBV genome. The EBV-encoded IL-10 (viral IL-10) is located on the BCRF sequence (the gene sequence of the Epstein–Barr virus) and the protein has maintained some, but not all, the biological activities of its cellular counterpart. IL-10 has 90 percent homology at the amino acid level with viral IL-10 (de Waal Malefyt 2000).

IL-10 regulates many aspects of inflammatory and immune responses and acts on both hemopoietic and nonhemopoietic cells. It has dominant suppressive effects on the production of proinflammatory cytokines by monocytes and neutrophils, and downregulates the expression of activating and costimulatory molecules on monocytes and dendritic cells (Fiorentino et al. 1991). This is the reason why it has also been defined as ‘macrophage deactivating factor’. IL-10 strongly inhibits the production of cytokines and chemokines by activated monocytes/macrophages. In addition, IL-10 enhances the production of IL-1Ra expression, as well

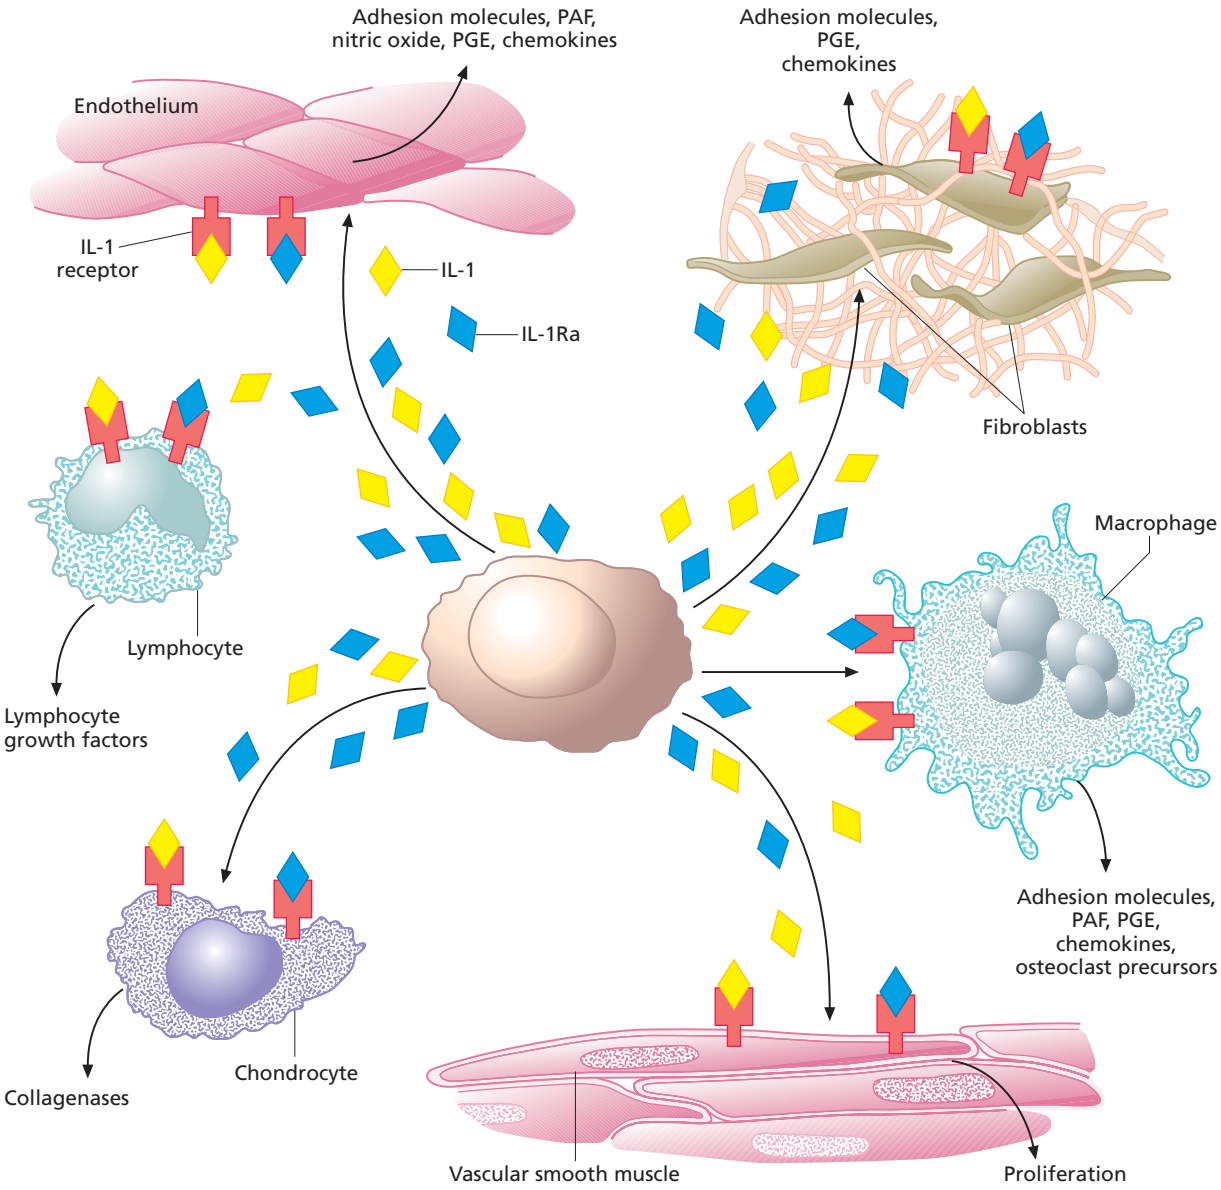

Figure 12 *The actions of interleukin 1 (IL-1) and its receptor antagonist (IL-1Ra). IL-1 activates its receptor on cells resulting in various functions. When IL-1R is occupied by the IL-1Ra, IL-1 cannot bind and thus cannot elicit a biological response. This is a natural balance between the proinflammatory activities of IL-1 and the ability of IL-1Ra to keep those activities in check by occupying IL-1Rs. PAF, platelet-activating factor; PGE, prostaglandin E. (Redrawn from Dinarello 2000c, with permission)*

as of soluble p55 and p75 TNFRs, indicating that IL-10 induces a shift from production of proinflammatory to anti-inflammatory mediators. IL-10 also inhibits expression of MHCII antigens, CD54 (ICAM-1), CD80 (B7), and CD86 (B7.2) on monocytes, even following induction of these molecules by IL-4 or IFN. IL-10 inhibits production of PGE_2, another proinflammatory mediator, as well as the ability of monocytes/macrophages to modulate turnover of extracellular matrix, an effect that is mediated by the inhibition of the production of gelatinase and collagenase, and the increase in the production of tissue inhibitor of metalloproteases. IL-10 also inhibits LPS-induced CRP biosynthesis.

Furthermore, IL-10 inhibits production of IL-12 and expression of costimulatory molecules on various types of dendritic cells. IL-10 also inhibits the production of chemokines, proinflammatory cytokines, and mediators of granulocyte survival, thus limiting the duration of inflammatory responses. IL-10 exhibits growth factor activities on B cells and mast cells, and inhibits or enhances the activities of $CD4^+$ and $CD8^+$ T cells depending on their activation conditions. IL-10 enhances the survival of normal human B cells (depending on their activation state), which correlated with increased expression of the antiapoptotic protein Bcl-2 and strongly increases the proliferation of human B-cell

precursors and mature activated B cells. Such effects of IL-10 may play a role in pathogenesis of systemic lupus erythematosus (SLE), where positive correlations between serum IL-10 levels and severity of disease, and between the production of IL-10 and autoantibodies by the SLE patient's B cells, have been demonstrated. IL-10 strongly inhibits cytokine production and proliferation of T cells and T-cell clones activated in the presence of APCs. This effect of IL-10 results mostly from its downregulatory effects on APC functions. The effects of IL-10 on individual cell types suggest that it could have potent anti-inflammatory/immunosuppressive activities in vivo in chronic inflammatory disorders, autoimmune disorders, and infectious diseases (de Waal Malefyt 2000).

Interleukin 10-related cytokines

Recently, five novel IL-10-related molecules and their receptors have been identified in blood mononuclear cells. These cytokines have been named IL-19, IL-20, IL-22, IL-24, and IL-26 (Gallagher et al. 2000; Dumoutier et al. 2000, 2001; Blumberg et al. 2001; Caudell et al. 2002; Wolk et al. 2002). Similar to IL-10, they are secreted α-helical proteins, the amino acid sequences of which are up to approximately 30 percent identical to those of IL-10 and comprise a definite position for cysteine. Of note, the encoding genes are located in the humane genome in two clusters, one comprising the genes for IL-10, IL-19, IL-20, and IL-24 on chromosome 1q32, and another comprising the IL-22- and IL-26-encoding genes located on chromosome 12q1 (Dumoutier et al. 2001)

IL-19 and IL-20 were found to be preferentially expressed in monocytes, whereas IL-22 and IL-26 (AK155) expression was exclusively detected in T cells, especially on Th1 polarization, and in NK cells (Wolk et al. 2002). IL-24 (melanoma differentiation-associated gene 7) expression was restricted to monocytes and T cells. Detection of these molecules in lymphocytes was predominantly linked to cellular activation. With regard to T cells, IL-26 was primarily produced by memory cells, and its expression was independent of costimulation.

In contrast to the extensively studied IL-10, the knowledge of the biology of the novel IL-10 homologs is still fragmentary. Preliminary functional data exist for IL-20, IL-22, and IL-24. Overexpression of IL-20 induced neonatal lethality, psoriasis-like skin abnormalities, lack of adipose tissue, and elevated apoptosis of thymic lymphocytes. IL-22 was suggested as playing a role in inflammatory processes through the observation that it induces acute phase reactant production in a hepatoma cell line and in vivo. Overexpression of IL-24 via adenovirus gene transfer induced growth inhibition in various tumor types. No function is known for IL-19 and IL-26 as yet.

However, although immune cells exhibit a differential expression of the IL-10 homologs, in contrast to IL-10 that is produced by and acts on all monocytes, NK cells, B cells, and T cells, these cells do not seem to be the major target population of these molecules.

Interleukin 13

IL-13 is secreted as a monomeric peptide of 10 kDa (McKenzie and Matthews 2000). Of note, the amino acid sequences of IL-13 and IL-4 are approximately 30 percent homologous, a level of similarity that is not evident among any other interleukins. The human IL-13 gene is located on the long arm of human chromosome 5 (5q31), where it is closely linked to the genes encoding IL-4, IL-5, IL-3, and GM-CSF. Indeed, the IL-13 gene maps approximately 12 kb upstream of the IL-4 gene (Figure 13) and there is a coordinate regulator of IL-4, IL-13, and IL-5 (Loots et al. 2000).

IL-13 is mainly produced by $CD4^+$ Th2 cells and clones. However, Th1 cell clones, Th0 cell clones, and $CD8^+$ T-cell clones, have also been shown to express IL-13 mRNA. Primary mouse mast cells and mouse and human mast cell lines have also been shown to express IL-13 in response to activation, and primary mouse NK cells and the human NK cell line NK3.3 secrete IL-13 in response to activation. IL-13 gene transcription has also been detected in a number of B-cell malignancies (McKenzie and Heath 1996).

IL-13 has been shown to have anti-inflammatory functions on monocytes and macrophages and to induce B cells to proliferate and isotype switch to the production of IgE. Blockage of IL-13 activity has been shown to inhibit the pathophysiology of asthma. Studies using IL-1 gene-deficient mice have identified impaired Th2 cell development in the absence of IL-13 and indicated an important role for IL-13 in the expulsion of parasitic gastrointestinal helminths. The anti-inflammatory function of IL-13 is manifested in its ability to suppress the expression of cytokines such as IL-1α and IL-1β, TNF-α, IL-8, and IL-12. Significantly, by inhibiting IL-12, it may also act to skew the T-helper populations away from a Th1 phenotype and towards a Th2 phenotype. IL-13 expression correlates strongly with the occurrence of allergic asthma and atopy, and the associated expression of IgE. Recent studies using mouse models of experimental nairway hypersensitivity have demonstrated that IL-13 plays a central role in these responses. On the other side, the anti-inflammatory roles of IL-13 may be important in controlling inflammation, such as that encountered in osteoarthritis. Interestingly, IL-13 has recently been demonstrated to be secreted by, and stimulatory for the growth of, Reed–Sternberg cells. Administration of recombinant IL-13 to IL-13-deficient mice or severe combined immunodeficient (SCID) mice resulted in improved expulsion of *Nippostrongylus brasiliensis* from helminth-infected animals, although the

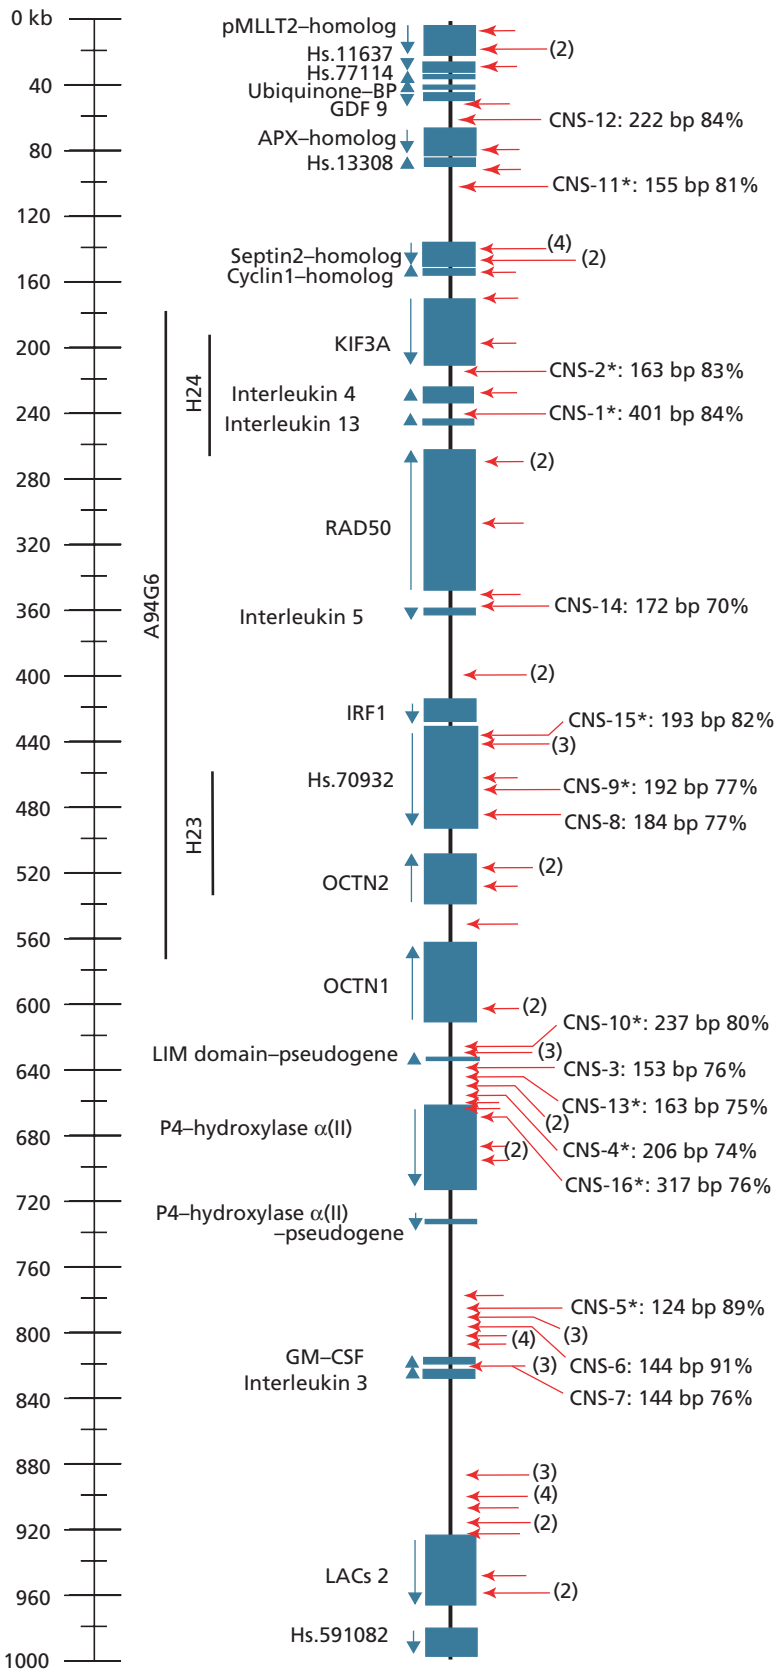

Figure 13 *The chromosomal association of interleukin IL-13 with other T-helper type 2 (Th2) cytokines, as shown by the physical map of the 1-Mbp human 5q31 region. (From Loots et al. 2000.)*

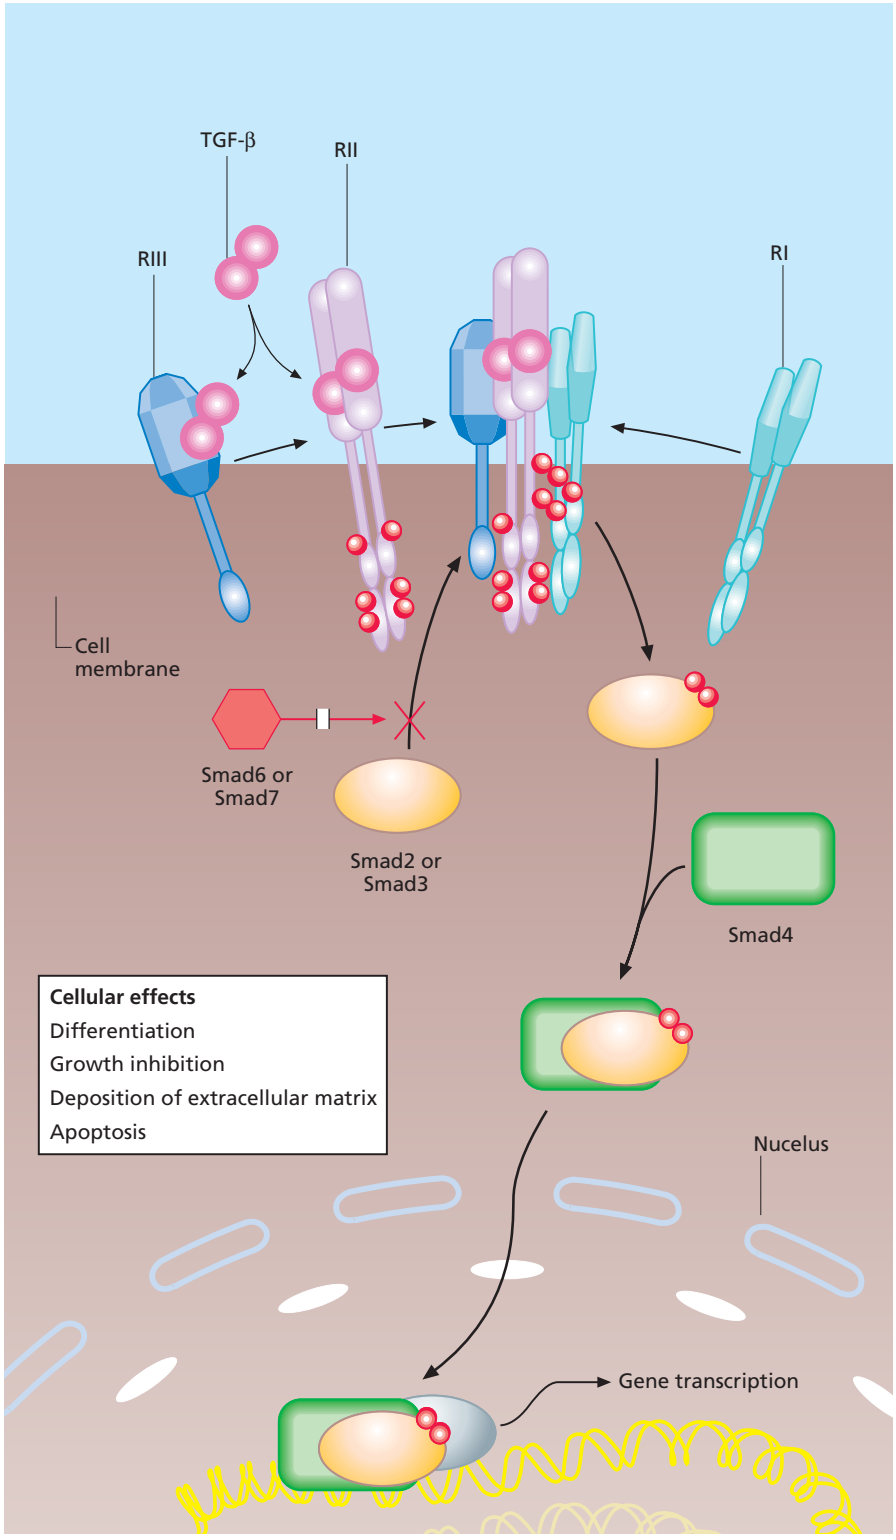

Figure 14 *Mechanisms of signal transduction and cellular effects of transforming growth factor β (TGF-β). In the extracellular space TGF-β binds either to the type III TGF-β receptor (RIIi), which presents it to the type II receptor (RII), or directly to RII on the cell membrane. The binding of TGF-β to RII then leads to binding of the type I receptor (RI) to the complex, and the phosphorylation of RI initiates the cascade of transcription factors that regulate the transcription of TGF-β-responsive genes and mediate the effects of TGF-β at the cellular level. (Redrawn from Blobe et al. 2000, with permission.)*

mechanism for this clearance is still unclear. As a result of its anti-inflammatory roles, IL-13 treatment has been used in models of collagen-induced arthritis and uveitis, and LPS-induced endotoxemia (McKenzie and Matthews 2000).

TGF-β

Three different isoforms of TGF-β (TGF-β_1, TGF-β_2, and TGF-β_3) exist as stable 25-kDa homo- or heterodimers crosslinked by a single disulfide bond that is formed by cysteine 77 of each monomeric unit (Flanders and Roberts 2000). TGF-β is secreted in noncovalent association with its own prodomain (latency-associated protein (LAP)) in a 'latent' form that is unable to bind receptors until activated. Whereas in other TGF-β family members the divergent N-terminal region of the unprocessed precursor serves only to facilitate proper folding and secretion of the mature peptides, for the TGF-βs, the LAP protein serves a unique role of conferring latency and effectively masking the receptor-binding domains of the molecule (Gleizes et al. 1997). The three TGF-β species are encoded by unique genes located on different chromosomes. All three genes share a similar intron/exon structure with a total of seven exons spanning greater than 100 kb of genomic DNA.

TGF-β is widely expressed in embryo tissues, whereas the major sources in adults are platelets, bone, and spleen (Thompson et al. 1989).

As almost every cell type can express receptors for TGF-β, its physiological and pathophysiological roles are extensive. The activity of the TGF-βs that distinguishes them from most other cytokines is their ability to limit cell growth. This growth inhibitory action is quite broad, targeting epithelial cells, endothelial cells, and hemopoietic cells. TGF-β also regulates the differentiated function of immune cells, acting as a strong suppressor of activation of T cells and of antibody secretion by B cells. Other major cellular targets for TGF-β action include its effects on chemotaxis (fibroblasts, lymphocytes, macrophages, and neutrophils) and its ability to control cellular differentiation, apoptosis, and extracellular matrix production. The last is the most prominent effect of TGF-β on mesenchymal cells, and is manifested by enhanced expression of extracellular matrix proteins, suppression of expression of matrix-degrading proteases, induction of expression of protease inhibitors, and regulation of expression of integrin receptors. Together, these effects result in increased accumulation of extracellular matrix and in cellular interaction with matrix (Figure 14). These many and varied cellular functions of TGF-β underlie its pathophysiological roles in fibrotic diseases, carcinogenesis, wound healing, autoimmune diseases, and parasitic diseases. TGF-β can be either synergistic and antagonistic to the action of other cytokines/growth factors, depending on the cellular context. Thus, TGF-βs play critical roles in normal physiology, most prominently in branching morphogenesis, in the transformation from epithelial to mesenchymal, control of cell growth, chemotaxis, and elaboration of extracellular matrix (Letterio and Roberts 1998).

The widespread expression of TGF-β coupled with its multiple bioactivities leads to its involvement in the pathology of many human diseases, such as fibrotic disorders, acute experimental allergic encephalomyelitis, and collagen-induced arthritis. TGF-β antagonists may be useful not only in these conditions, but mainly in reducing tumor growth, possibly by inhibiting the immunosuppressive effects of TGF-β. Clinical applications for TGF-β are limited by the difficulty to find optimal methods of delivery and ensure its bioavailability (Flanders and Roberts 2000)

Antibody molecules are the functional products of the humoral arm of the mammalian immune system. They are glycoprotein molecules found mainly in the γ fraction of serum, and are members of the immunoglobulin (Ig) family of serum proteins. Although Ig molecules exist as five classes, each with distinctive structural and functional properties, all Ig molecules conform to a common unit structural theme, the four-chain model (Figure 1), which provides a molecular explanation for their immunological activities. Antibody molecules are synthesized by B lymphocytes.

The humoral response is one arm of the specific, adaptive, immune response, and is characterized by the diversity of individual specific antibodies that it can produce, immunological memory, and production of antibodies of the most appropriate type to combat particular pathogens. The humoral response interacts with the cellular immune response and also interfaces with components of the nonspecific immune system. Thus, the nonspecific immune system, which shows no specificity or immunological memory, possesses potent cytotoxic power in the form of phagocytic cells and the components of the complement cascade. The humoral response has essentially no toxic capacity in its own right, but uses antibody specifically to recruit the cytotoxic power of the nonspecific system and focus it at the pathogen target.

The humoral immune response displays characteristic features. After initial challenge with antigen, levels of antibody of the IgM class rise over some 4–7 days; this is the primary humoral response. If antigenic challenge persists, antibodies of other classes, notably IgG, are produced; this is the secondary response. Second or subsequent challenge with the same antigen elicits a response that is more rapid than the primary response, and generates greater quantities of specific antibody of greater quality (i.e. different class and higher affinity) from those found in the primary response. The capacity to respond to re-challenge by a given antigen is long-lived and resides in memory B cells. The secondary response encompasses antibody responses, the major components of which are of the IgA, IgD, IgE, or IgG classes.

IMMUNOGLOBULIN STRUCTURE

The four-chain model

The four-chain model describes the overall structure of IgG molecules (Porter 1962), and this structural theme is common to all five Ig classes. The general features of the four-chain model are illustrated in Figure 1, using human IgG1 as an example. Antibody molecules are composed of two identical heavy chains, disulfide bonded to two identical light chains in such a way that the amino terminus of each heavy and light chain is juxtaposed in three-dimensional terms to generate the

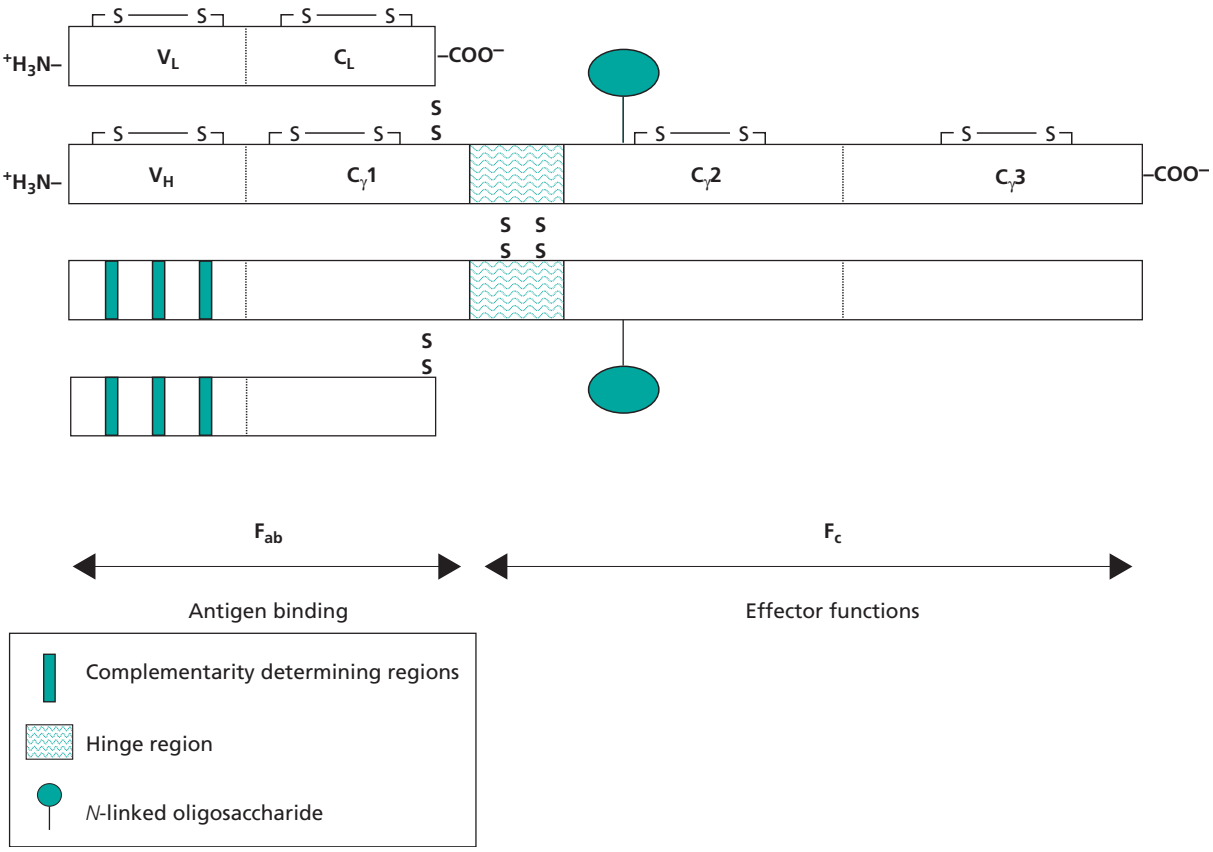

Figure 1 *The four-chain model: the arrangement of an IgG1 molecule is shown. The hypervariable regions/complementarity determining regions are shown as solid rectangles in the V domains. The hinge region is illustrated as a patterned box and N-linked oligosaccharide by a filled circle. The locations of the Fab and Fc regions are noted.*

antibody-combining site. Interchain disulfide bonds link not only the heavy and light chains but also the two heavy chains together. The IgG molecule is bivalent with respect to antigen binding (Edelman and Poulik 1961; Porter 1962).

Controlled proteolysis of IgG molecules has provided insights into structure–function relationships by investigation of the distinct fragments of Ig molecules generated (see Figure 1). Papain cleaves the intact IgG molecule to release three fragments of approximately equal molecular weight. Two of these fragments, derived from the amino terminus of the molecule, are identical and, because they retain antigen-binding capacity, are referred to as Fab (fragment antigen binding) fragments. Fab fragments are monovalent with respect to antigen binding and, as such, are unable to form immunoprecipitates in solution or in semi-solid media. The remaining product of papain digestion, the Fc (fragment crystalline) piece, is derived from the C terminus of the intact IgG molecule, and has no antigen-binding capacity. It is, however, of considerable importance in expression of antibody effector functions.

Pepsin digestion of intact IgG yields quite different proteolysis products. A large fragment of about 100 kDa is the main product, the remaining material usually being small peptides. The l00-kDa fragment is derived from the amino terminus of the intact IgG, has antigen-binding capacity, and is bivalent (i.e. possesses two equivalent antigen-combining sites). This is the $F(ab)'_2$ fragment.

Primary structure

Primary protein structure is the linear arrangement of amino acids in the polypeptide chain. Initial sequencing studies of Ig molecules were performed using Bence–Jones proteins, which are monomeric or dimeric light chains derived from the urine of patients with multiple myeloma (Edelman and Gally 1962). Primary sequence analysis of Bence–Jones light chains revealed that they were divisible into two distinct regions of approximately equal size. Thus, from amino acid 1 (the amino-terminal residue) to amino acid 107, the sequence of one Bence–Jones protein was different from that of any other Bence–Jones protein with which it was compared, whereas the sequences from residues 108 to 214 were essentially identical for all Bence–Jones proteins. These observations led to the division of light chains into variable (V) and constant (C) regions on the basis of the variability of amino acid sequence within the protein (Milstein 1966).

A similar structural division can be made for heavy chains. As described for the light chains, the amino-terminal regions of the heavy chains possess considerable variability from one chain to another, but the carboxy-terminal regions are relatively constant. In the case of the heavy chains, however, the variable region extends from residue 1 to residue 113, and the constant region from residue 114 to the carboxyl terminus, which may be some 400 amino acid residues distant in the primary sequence. Furthermore, when the sequences of heavy chain C regions are analyzed, it is clear that there are areas of significant homology of primary sequence along the length of the C region. The sequence can be subdivided into units of homology of approximately 100–110 amino acids. The functional importance of these domains is discussed below in the context of tertiary structure.

The V regions of both heavy (V_H) and light (V_L) chains have numerous amino acid substitutions when individual polypeptide chains are compared. However, plots of variability of amino acid versus position in the primary sequence reveal that the distribution of amino acid substitutions is not random, and that the variability is clustered in small regions of the primary structure. These areas of the V region are the hypervariable regions and they provide a molecular explanation for antibody specificity. Thus, the V_L and V_H regions of an individual antibody molecule are unique and the recognition of antigen by that antibody is similarly distinctive. As the hypervariable regions govern the specificity of the antibody molecule, they are sometimes referred to as complementarity determining regions (CDR).

Both heavy and light chains possess three CDRs. The heavy chain CDRs are located at positions 26–36, 55–65, and 95–105 in the primary sequence, and are referred to as CDR H1–3, respectively. The light chain CDRs (L1–3) are positioned at residues 25–35, 54–67, and 94–108. The above numbering is based on the EU myeloma protein (Edelman et al. 1969). Outwith the hypervariable regions, or CDRs, the primary sequence of the V region is largely conserved between molecules. These conserved regions are crucial in the maintenance of the higher structure of the V_H and V_L regions and are therefore termed 'framework regions'.

Secondary and tertiary structure

Secondary structure is the relationship between amino acids located some distance apart in the primary structure, the interactions of which give rise to periodic structural motifs in the folded protein molecule (e.g. α helix or β-pleated sheet structures). Ig molecules contain no α-helical structures but are rich in β-pleated sheets. Tertiary structure also describes the spatial relationship of amino acids which are distant in the primary sequence and, for the purposes of this discussion, refers to those cysteine residues in the primary sequence that form intrachain disulfide bridges, giving rise to individual domains within the Ig molecule.

The 'Ig-like fold' or domain is a characteristic higher structural motif of Ig structure. The primary structural data indicate that the sequences of Ig chains are divisible into homology units of approximately 110 amino acids in length. Within each of these units lies a single disulfide bridge, enclosing 65–75 residues in the V regions and 52–59 residues in the C-region domains. Clearly, the location of the cysteine residues is critical in domain formation, and this is reflected not only in the conservation of this amino acid at defined positions in the polypeptide chain, but also by the conservation of primary sequences surrounding the cysteine groups participating in intrachain disulfide bond formation.

The domain structure produced by disulfide bond formation is rich in β-sheet structure, with each domain in both the V and the C regions of the Ig molecule containing two β sheets. In each β sheet, the polypeptide structure may be considered as layers of overlapping sequence lying parallel to the long axis of the domain, one layer containing three strands of polypeptide and the other four strands. The polarity of adjacent, individual strands is anti-parallel, and the two layers of β strands are joined by the single disulfide bond. Multiple, hydrophobic, amino acid, side-chain groups protrude into the space between the layers.

Quaternary structure

Quaternary structure reflects the interaction between distinct polypeptide subunits of a multidomain protein. In Ig molecules the interaction between particular domains is well defined and correlates well with biological activity. Thus, V_H and V_L domains interact to yield the correct conformation for generation of the antigen-combining site. C_L and C_H domains also interact. In the C region, like domains interact. Thus, Cγ2 interacts with Cγ2 and Cγ3 with Cγ3. However, the interaction does not always involve direct contact between the faces of the two participating domains. In IgG molecules the Cγ2 domains are separated from each other by the large oligosaccharide unit located in this domain, whereas Cγ3 domains interact via contacts between faces of the two domains.

The forces that stabilize domain–domain interactions are noncovalent in character and involve weak intermolecular physical forces (i.e. hydrophobic interactions, salt bridges, hydrogen bonding). Although the physical forces that mediate domain interaction are identical for V and C domains, the faces of the protein that interact are distinct. Thus, V domains interact via those layers of the domain containing three strands of peptide sequence, whereas the C domains interact via the layers containing four strands of polypeptide.

The detailed higher structure of Ig molecules is discussed in under 'Structural biology of Ig and Ig receptors' below.

Other structural features

The hinge region of IgG molecules is of critical importance to their function; located between the Cγl and Cγ2 domains, it is rich in proline and cysteine residues. The size of the hinge region varies from one IgG subclass to another, being 10–20 residues in length in all subclasses except IgG3 where it is 60 residues long (Figure 2). This area of the Ig molecule has considerable segmental flexibility, which is important in the expression of the effector functions of IgG molecules, e.g. the greater the segmental flexibility of a given immunoglobulin isotype, the more likely it is that complement can be effectively fixed (Oi et al. 1984). The positioning of the hinge region is such that it allows the Fab arms of the IgG to adopt a wide range of orientations with respect to each other; this feature also explains the characteristic 'Y' shape of IgG molecules visualized in antigen-binding experiments in the electron microscope (Valentine and Green 1967). The hinge region is the location of the inter-heavy chain disulfide bonds in the IgG molecule, the exact number of which varies between IgG subclasses. Thus, IgG1 and IgG4 have two interchain disulfide bridges, IgG2 has four, and IgG3 15. The region is also exposed to the solvent, with the consequence that proteolytic enzymes may attack it and generate fragments as described earlier in this chapter.

Ig molecules contain varying amounts of carbohydrate. In most instances the glycans are attached to asparagine residues (so-called N-linked oligosaccharides), but carbohydrate is also found linked to the hydroxyl groups of serine or threonine residues (O-linked sugars) in human IgD molecules and in the hinge region of human IgA molecules. In IgG molecules the principal site of glycosylation is asn297, and the N-linked oligosaccharide is usually a complex structure with two branches of linear sugars originating at a single point, although the precise oligosaccharide structure can vary enormously between individual IgG molecules. The presence of certain types of carbohydrate structure has been correlated with particular autoimmune disease states (Parekh et al. 1985), but the role of the N-linked glycans themselves in disease pathogenesis remains unclear. The other Ig isotypes are multiply glycosylated (Winkelhake 1978).

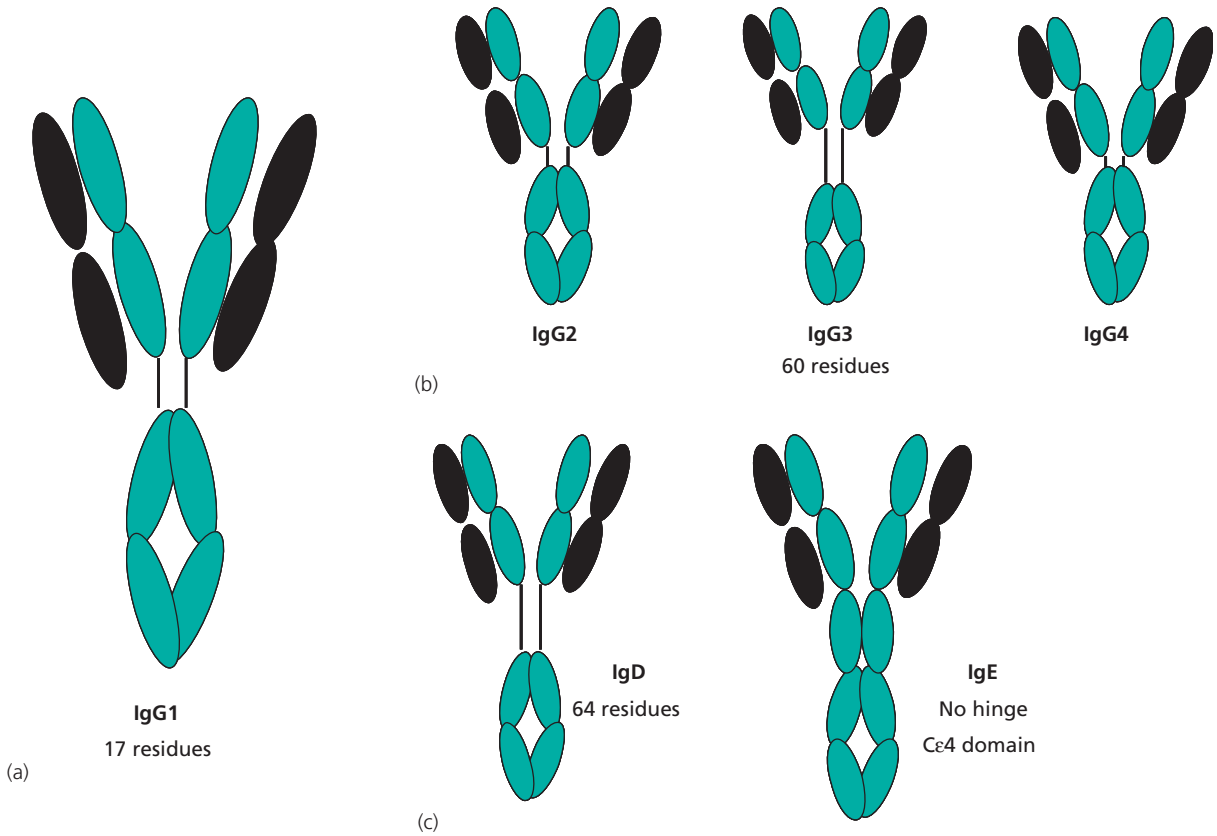

Figure 2 *Monomeric immunoglobulins: the layout of the domains in the heavy and light chains of IgG, IgD, and IgE molecules is illustrated. The light chain domains are illustrated as filled, black ovals in all cases. IgG1 is illustrated as the largest element in* **(a)**, *and each of the other IgG subclasses is illustrated with the hinge regions illustrated as solid lines of different sizes* **(b)**. *IgD and IgE molecules are shown in their 'extended' forms* **(c)**.

IMMUNOGLOBULIN CLASSES

Ig molecules exist as five classes, or isotypes, in humans, each of which has characteristic structural features and particular immunological activities. The serological marker that defines Ig class or subclass is the isotype, and the terms 'isotype' and 'class' (and 'subclass') are used interchangeably. All isotypes have a four-chain unit as their fundamental structural feature, and each class is named for the heavy chain of the molecule. Thus, IgG is named for the γ (gamma) heavy chain, IgM for the μ (mu) chain, and IgA for the α (alpha) chain. The principal molecular properties of the five human Ig classes are detailed in Table 1, and are illustrated diagrammatically in Figures 2 and 3.

IgM

IgM is a pentameric structure comprising five identical four-chain units, i.e. it has 10 identical binding sites. The μ heavy chain has five domains, V_H plus four C regions (Cμl, Cμ2, Cμ3, and Cμ4), and lacks a hinge region. The pentameric structure is stabilized by disulfide bonding between adjacent Cμ3 domains, and by the presence of the J (joining) chain. A single J chain is disulfide bonded close to the C terminus of the IgM pentamer (Chapuis and Koshland 1974). The critical cysteine residue (Cys575) is part of an 18 amino acid carboxy-terminal peptide extension located immediately following the Cμ4 domain, and this residue forms disulfide bonds either with J chain or with cysteines located in an identical position in other μ chains of the pentameric complex (see Figure).

IgM is the principal component of the primary humoral response. As a result of its large size (970 kDa, 19 S), it is located mainly in the bloodstream. It is decavalent, leading to highly avid binding of antigens (thereby overcoming the potentially low affinity of the antibody–antigen interaction), and is efficient in both opsonization and complement fixation.

IgG

IgG is the main class of Ig in serum. As will be obvious from the detailed discussion of the four-chain model, it exists as a molecule of about 146–160 kDa (7 S) in serum, and is an abundant component of the secondary humoral immune response. This class of Ig is found not only in the bloodstream itself, but also in extravascular spaces. It is transported across the placental membrane and is therefore responsible for passive immunity in the fetus and neonate (see Figure 4).

There are four major subclasses of the IgG isotype in humans, each distinguished by minor variations in amino acid sequence in the C region and by the number and location of disulfide bridges (Figure 5 and see Figures 1 and 2). The structural variations have consequences for biological activity. Thus, the IgG1 and IgG3 isotypes are efficient in fixation of complement, whereas IgG2 and IgG4 subclasses are less effective in activating complement. There is a similar hierarchy among IgG subclasses in binding to different types of the Fc receptor (see 'Receptors for immunoglobulin' later).

IgA

IgA is found in two forms in the body: in serum where it occurs as a monomer (160 kDa, 7 S), and on secretory surfaces where it exists as a dimeric molecule (385 kDa, 11 S) (see Figure 3). The dimeric form is known as secretory IgA (sIgA) and is found in association with J chain and a secretory component, the latter being involved in transport of the IgA to the secretory surfaces. Secretory component is noncovalently associated with the IgA molecules in the sIgA complex. The α chain has three C domains and, as with μ chains, possesses an 18 amino acid carboxy-terminal sequence allowing disulfide bonding to the J chain. A small hinge region is also present. There are two subclasses of IgA, IgA1, and IgA2, distinguished by their distribution and

Table 1 *Molecular properties of immunoglobulins*

	IgM	IgG1	IgG2	IgG3	IgG4	IgA1	IgA2	sIgA	IgD	IgE
Heavy chain	μ	γ_1	γ_2	γ_3	γ_4	α_1	α_2	α_1/α_2	δ	ϵ
Mol. wt (kDa)	65	51	51	60	51	56	52	52 or 56	70	72.5

Serum concentration (mg/ml)	1.5	9	3	1	0.5	3	0.5	0.05	0.03	0.00005

a) Mol. wt. of J chain is 15kDa
b) Written as γ_2L_2 for convenience; formal structural formula is $(\gamma_1)_2L_2$
c) Mol. wt of secretory component (SC) is 70 kDa.

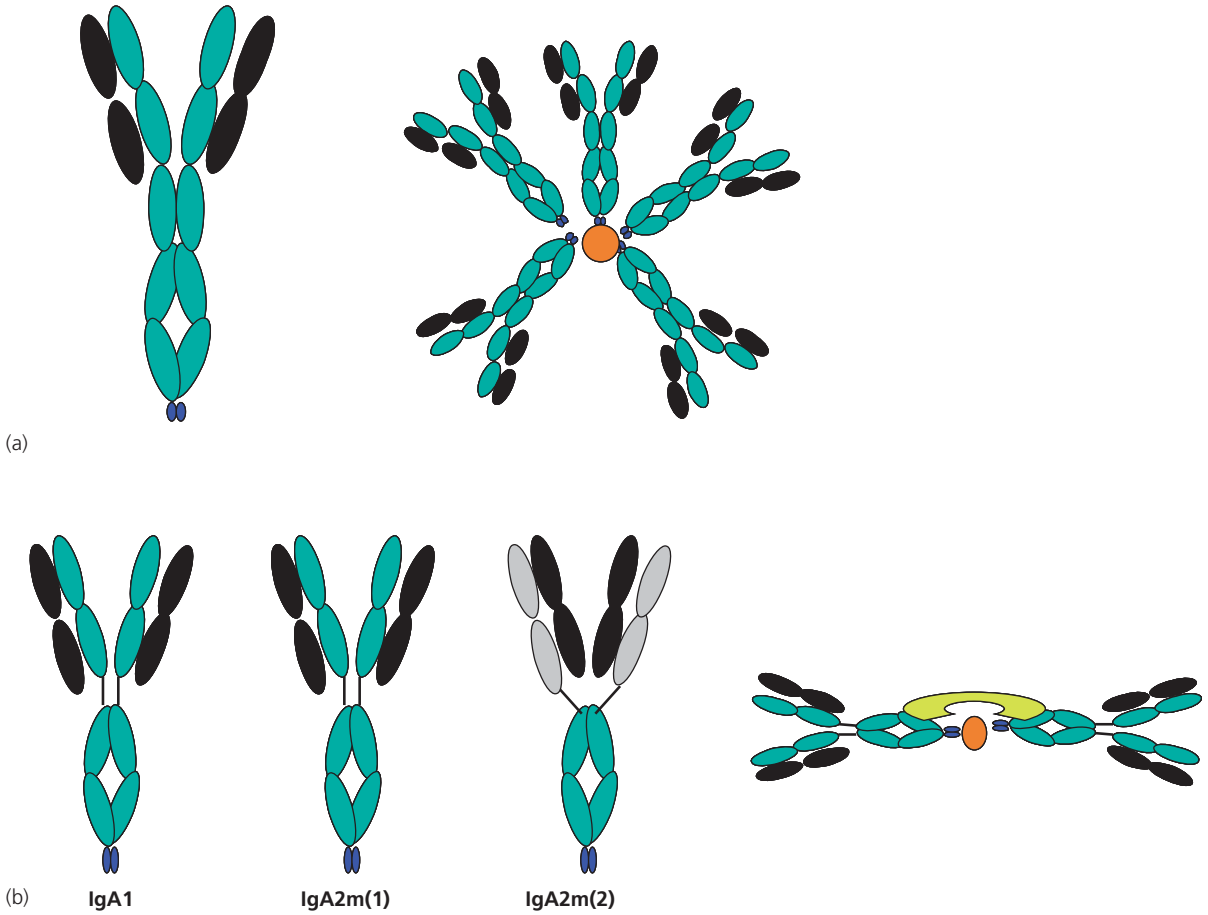

Figure 3 *Polymeric immunoglobulins: the monomeric forms of IgM* **(a)** *and IgA* **(b)**, *based on the four-chain model, are shown. Note the different location of the light chains in the IgA2m(2) molecule (an allele of IgA2). Polymeric forms of both Igs are illustrated, with a pentameric structure for IgM and a dimer for IgA. On polymeric IgM and IgA, J chain is shown as a red circle and on IgA, secretory piece is illustrated as a yellow 'C' shape bridging the two IgA monomers. The μ and α heavy chains each possess a small region of 18–20 residues that facilitates binding of J chain; this is illustrated as a small blue oval on the figures.*

arrangement of disulfide bonds. IgA1 is the predominant form of IgA found in serum (about 85 percent of total), whereas IgA1 and IgA2 isotypes are present in roughly equal proportions in sIgA; both the α1 and α2 heavy chains can interact with J chain and secretory component.

IgA is a component of the secondary humoral response. The principal antigens that elicit an IgA response are microorganisms in the gut (e.g. antigens introduced by foodstuffs) or the airways. IgA cannot cross the placenta, and so has no role in passive immunity in the fetus. However, sIgA can be passed to the neonate during lactation and is therefore of significant protective value because the IgA transferred by the mother will reflect immune responses to pathogens present in the environment throughout the period of breast-feeding.

IgE

IgE (about 184 kDa, 8 S), historically referred to as reaginic antibody, is present in very small amounts in normal individuals, but levels are increased in patients with allergic conditions (e.g. hay fever) or those with parasitic infections. The ϵ (epsilon) chain has four C domains (see Figures 2 and 5), and its Fc structure is specialized for interaction with high-affinity receptors for the Fc piece of IgE present on mast cells and basophils. Crosslinking of IgE bound to such Fc receptors leads to degranulation of the cell, with subsequent release of histamine and other pharmacological mediators (Ishizaka et al. 1971; Sutton and Gould 1993; Metzger 1994, 1999), triggering a series of physiological reactions that can result in anaphylaxis. Thus, IgE is a mediator of type I hypersensitivity reactions. IgE may have originally evolved to combat parasitic infestations (e.g. by helminths), and the development of anaphylactic responses was an unfortunate byproduct. IgE does not fix complement via the classic pathway but may activate the alternate pathway. It is found in roughly equal proportions in the bloodstream and extravascular space.

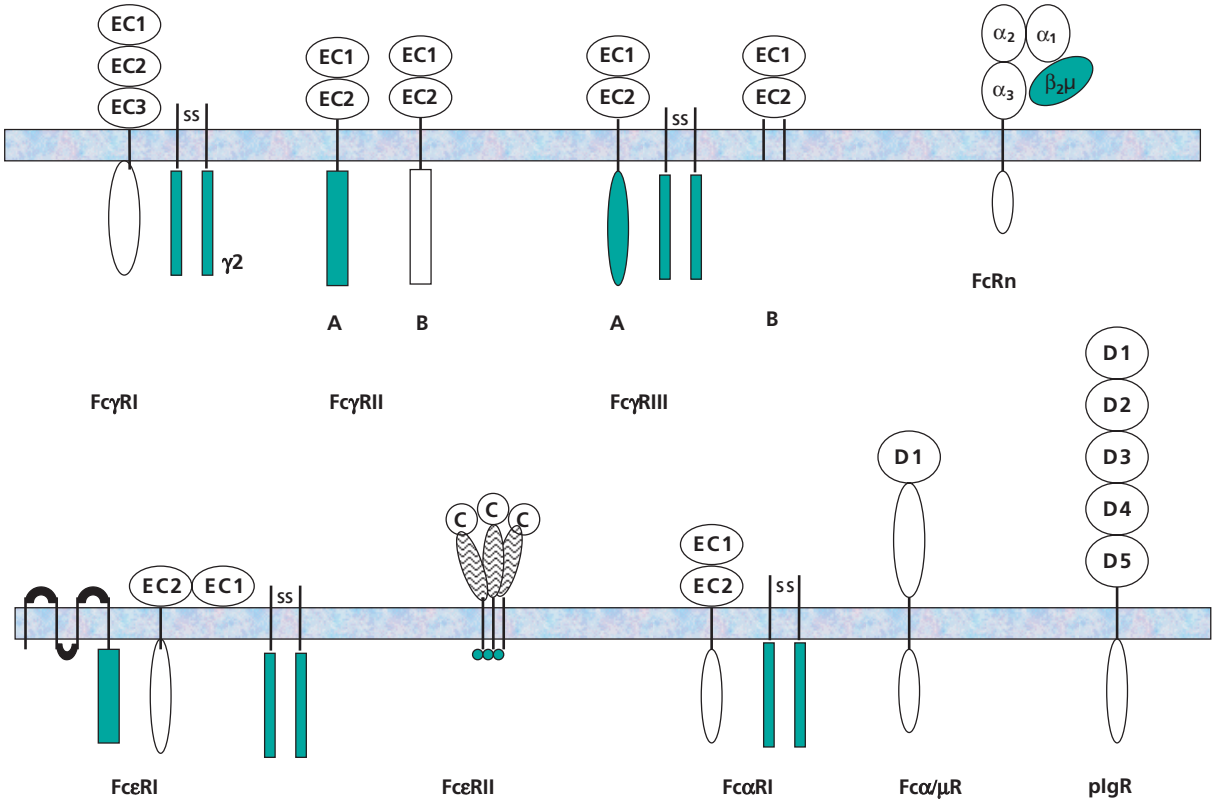

Figure 16.4 *Immunoglobulin receptors: the main classes of Fc receptor for IgG, IgA, IgM and IgE are illustrated. The upper panel shows receptors for IgG, and the lower panel receptors for other Ig isotypes. Each Ig-like extracellular domain (EC, or D in the main text) is shown as a circle, and the domains are numbered from the amino terminus of the receptor molecule. Note that FcγRIIIB is linked to the membrane via a glycophosphatidylinositol (GPI) anchor. ITAM (immunoreceptor tyrosine-based activation motif) and ITIM (immunoreceptor tyrosine-based inhibitory motif) intracellular domains are represented as filled and open rectangles, respectively. Intracellular domains with no or undefined signaling functions are shown as open ovals. FcεRIγ is depicted in a 'lying-down' orientation. For FcεRII, the C-type lectin domain is depicted as 'C' and the oval domain represents the stalk region.*

IgD

IgD is present in very low concentrations in the serum, and its exact functional role is unknown. The human δ heavy chain has three C domains (see Figure 16.2). IgD is most frequently found on the cell membrane of B lymphocytes, where its main function appears to be that of a cell membrane receptor for antigen. Human IgD does have a long hinge region of some 64 residues, and is rich in O-linked oligosaccharide groups; the extent of glycosylation explains its high apparent molecular mass (about 175 kDa). Unusually, the hinge region is encoded by two separate exons in the Cδ gene (White et al. 1985). The mouse, by contrast, has only two constant region domains, Cδ1 and Cδ3 (Preud'-homme et al. 2000). The functions of IgD are not greatly understood, although there are good numbers of IgD^+ plasma cells in nasal and tonsillar tissue. In disease terms, high levels of IgD are found in an autosomal recessive condition, hyper-IgD syndrome, which is linked to a mutation in mevalonate kinase (Drenth et al. 1999), but the links between Ig and isoprenoid synthesis are not clear.

Other immunoglobulin components

Light chains are found in two forms, kappa (κ) and lambda (λ), and any single antibody molecule contains only one type of light chain. The proportion of κ:λ in the human is 2:1, but this ratio varies considerably between species. The κ and λ proteins are products of independent genes located on different chromosomes.

J chain is a glycoprotein of about 15 kDa associated with polymeric Igs (i.e. IgM or IgA, see Figure 16.3), which serves to stabilize the structure of the polymerized immunoglobulins (Chapuis and Koshland 1974). Secretory component is a glycoprotein of about 70 kDa found almost exclusively in sIgA (see Figure 16.3), although association of secretory component with IgM, to yield secretory IgM, has been described in patients with IgA deficiency (Thompson 1970). The association of secretory component with IgM molecules is a reflection of the initial identity of secretory component as a polymeric immunoglobulin receptor (pIgR) on the basolateral surface of epithelial cells. Thus, secretory component, an important component of the sIgA molecule, is not a biosynthetic product of B cells. The immunobiology of

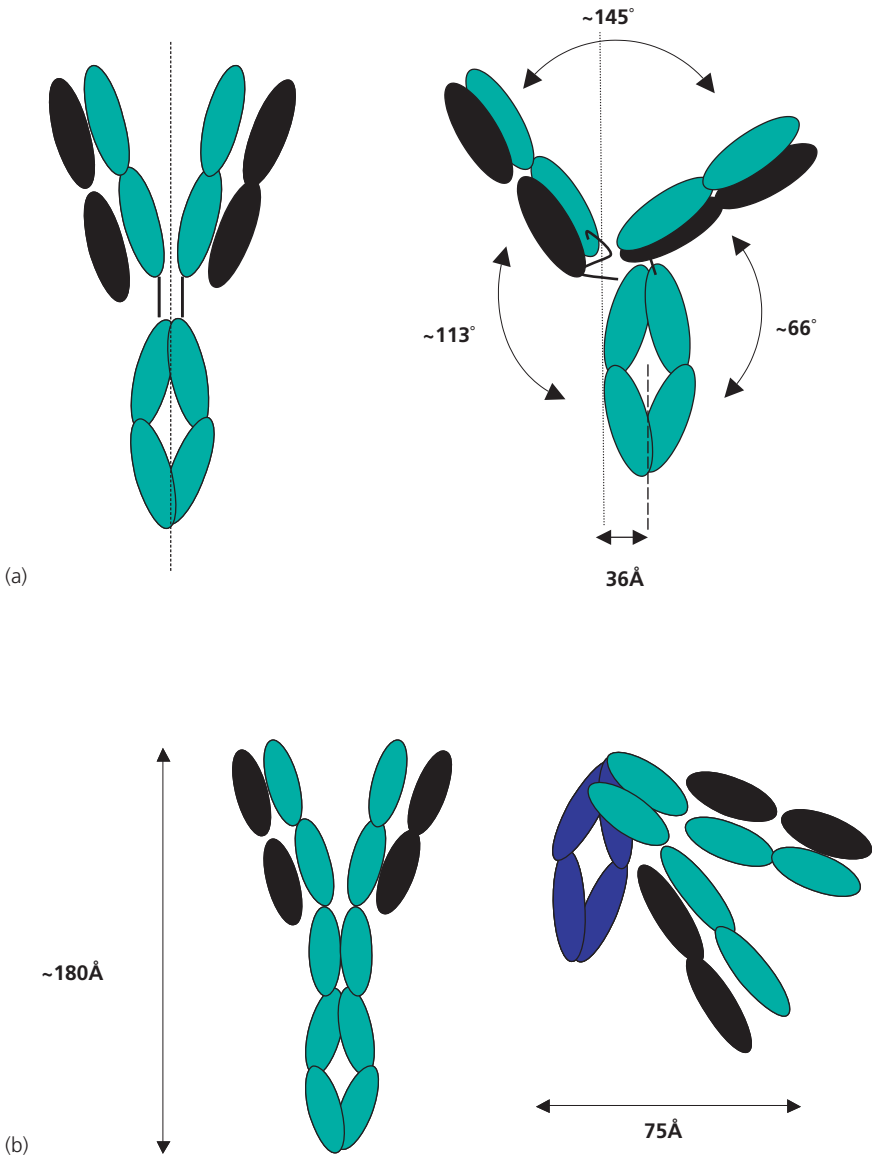

Figure 5 *Structures of IgG and IgE re-visited: the disposition of domains on IgG* **(a)** *based on crystallographic data from the b12 monoclonal antibody (MAb) are sketched and approximate sizes and relative angles of domains illustrated. The broken lines in the IgG cartoons represent the main axis of symmetry through a 'symmetrical' IgG molecule, to illustrate the 3.2 nm offset of the Fc domain in b12. Equivalent cartoons for IgE* **(b)** *are based on crystallographic analysis of the Cε2/Cε4 Fc region of human IgE. For IgE Cε2–Cε4, the Cε3 and Cε4 domains are shown in blue.*

pIgR is discussed under 'The polymeric immunoglobulin receptor' later).

Immunoglobulin metabolism

Immunoglobulins are being constantly synthesized, secreted into the circulation, and catabolized (Table 2). Once secreted into the extracellular environment, each Ig isotype has a characteristic metabolic half-life, with IgG molecules tending to be the longest-lived species, and IgE molecules being most rapidly cleared from the circulation (Table 2). The rate of synthesis of IgG molecules in humans is 33 mg/kg per day, i.e. more than 2 g/day for a 70-kg man. IgG molecules are generally relatively long-lived in the circulation, with a half-life of approximately 21 days; IgG3 has a half-life of 7 days. The fractional catabolic rate of IgG molecules, or the percentage turned over per day, is of the order of 17 percent (7 percent for IgG3). During an active immune response, the amount of specific antibody synthesized in terms of micrograms of protein is quite small, and represents only a minor fraction of the total IgG present in the serum. Therefore, initiation of a vigorous humoral immune response does not make a large impact on the total serum concentration of Ig. The catabolism of Ig is regulated by the Fc region and involves both protein and oligosaccharide components (Winkelhake 1978).

Table 2 *Metabolism of immunoglobulins*

	IgM	IgG1	IgG2	IgG3	IgG4	IgA1	IgA2	IgD	IgE
Serum concentration (μg/ml)	1500	9000	3000	1000	500	3000	500	30	0.05
Distribution (%)[a]	80	45	45	45	45	42	42	75	50
Synthetic rate (mg/kg per day)	3.3	33	33	33	33	24	24	0.4	0.002

a) Distribution is expressed as the percentage of intravascular immunoglobulin.
b) Fractional catabolic rate is expressed as the percentage of the intravascular pool catabolized per day.

Membrane immunoglobulin

B lymphocytes express a receptor form of antibody, membrane immunoglobulin (mIg), on their cell surfaces. As required by the clonal selection hypothesis, the receptor antibody is identical in essentially all respects to the antibody that will be secreted by the B cell on contact with antigen. The sole difference is the presence of a hydrophobic sequence at the carboxy-terminus of the heavy chain which allows stable insertion into the plasma membrane. The mIg forms part of the B-cell antigen receptor complex (BcR), and is found associated with other proteins at the cell membrane. It should be noted that the mIg molecule is always found as a single four-chain unit; thus, primary B cells synthesizing IgM express a single four-chain mIgM unit at their cell surface although, once activated by antigen, they secrete a polymeric IgM containing five four-chain IgM units. The mIg-associated proteins are transmembrane proteins of 34 kDa (Ig-α) and 37 kDa (Ig-β) which have functions in efficient transport of the mIg molecule to the cell surface and in linking the BcR to the intracellular signaling machinery of the B lymphocyte. The Ig-α and Ig-β proteins form a disulfide-bonded complex with each other, and associate noncovalently with the mIg molecule (Reth 1995). The mechanisms of intracellular signaling triggered by the BcR are extremely complex, and involve recruitment of soluble protein tyrosine kinases, activation of inositol lipid hydrolysis, and calcium mobilization. The biological response of the B cell to binding of antigen to the BcR depends on the state of differentiation of the B cell (see The B cell antigen receptor).

BIOLOGICAL EFFECTOR FUNCTIONS OF IMMUNOGLOBULINS

Range of effector functions

Antibody molecules by themselves are not directly cytotoxic toward invading pathogens. In most cases, the humoral immune system depends on the recruitment of other cytotoxic systems that can eliminate invading organisms, once specifically directed to the target by antibody. Consequently, antibody molecules participate in a wide variety of effector functions (Table 16.3). These activities are triggered after binding of specific antigen, and can involve a wide range of serum proteins, lymphocytes, and nonspecific inflammatory cells. Thus, the complement cascade is readily activated by immune complexes containing antibodies of particular subclasses. The Fc portion of immunoglobulins can be bound by specific receptors on the plasma membranes of a wide range of cells, and this interaction has consequences for phagocytosis of target organisms, or for direction of antibody-dependent cellular cytotoxicity (ADCC) for the destruction of cellular targets. Studies with fragments of Ig molecules and with monoclonal antibodies (MAb) to specific domains of the IgG molecule have demonstrated convincingly that the expression of

a) Activation of the alternate pathway.

effector functions is mediated by the Fc portion of the immunoglobulin molecule.

Neutralization

Neutralization is a direct consequence of the binding of antibody to an antigen and is an important means by which antibodies protect the host against disease. Many pathogens mediate their effects by elaborating toxic agents that bind to specific receptors on target tissues to induce a biological response or, in the case of viruses and intracellular bacteria, utilize cell-surface structures to gain entry to cells where replication can occur. In such circumstances, a protective antibody is one that specifically interferes with the interaction of the toxin or pathogen with a cell-surface receptor. In an immune response to a single agent, a large array of antibodies is produced which can bind at distinct sites (called epitopes or determinants) on the foreign protein or pathogen. Taking a toxin as an example, if an antibody binds to the toxin at an epitope that is required by the toxin for interaction with a cell-surface receptor, the antibody sterically hinders this binding of the toxin. The antibody is said to neutralize the biological activity of the toxin because the toxin cannot bind to the receptor and so no pathology or disease develops. The same applies to neutralizing antibodies specific for viruses; if antibody blocks the interaction of a virus with a receptor, the virus cannot enter a cell and consequently no replication occurs and no overt disease develops. A goal of vaccine strategies is therefore to induce the production of neutralizing antibodies in the immunized host. This has been studied at the crystallographic level using the b12 antibody directed against the HIV gp120 protein (Saphire et al. 2001b). The data show clearly that the binding site of the antibody, particularly the CDR3 of the heavy chain, mimics the CD4 natural ligand for gp130 by having a tryptophan residue protruding into space to fill a pocket in gp130 normally occupied by phenylalanine of CD4 (see 'Structure of human IgG1: the b12 anti-HIV-gp120 MAb' later).

Complement fixation

The classic pathway of complement activation is readily triggered by immune complex formation, although not all isotypes are capable of participating in this reaction (see Table 3). Thus, IgM is a potent activator of complement but IgA is unable to activate the classic pathway. It should be noted, however, that aggregated IgA, and possibly IgE, molecules may activate the alternate pathway of complement fixation. The capacity to activate the complement cascade depends on the ability to interact with the Clq component and, in the case of IgG molecules, on the segmental flexibility of the molecule.

The point of interaction between IgG and Clq has been mapped to three residues: Glu318, Lys32, and Lys322 in the three-strand face of the Cγ2 domain (Duncan and Winter 1988). The carbohydrate group of IgG, located on Asn297, influences the effectiveness of complement fixation because absence of the oligosaccharide leads to a decrease in activation of the classic pathway, an effect that may be explained by a threefold increase in the dissociation constant for the interaction between IgG and Clq when nonglycosylated IgG molecules are used (Leatherbarrow et al. 1985). The biology of complement is discussed in detail in Complement.

RECEPTORS FOR IMMUNOGLOBULIN

Antibody molecules express a range of effector functions that are concerned with the elimination of the pathogen or antigen from the host. These functions can range from simple neutralization of function of an invading particle, to bringing about destruction and clearance of a pathogen by either activation of complement or binding to receptors for the Fc regions of individual immunoglobulin isotypes. Fc receptors (FcR) have a range of roles in the immune response, are generally isotype-specific in their binding to Ig, and show a high affinity for binding to the Fc regions of their target Ig (Table 4 and see Figure 4). Some FcRs show a preference for Ig in immune complexes whereas others can bind monomeric Ig with high affinity, and many FcRs exist, not only as membrane-associated molecules but also as soluble proteins that retain Ig-binding activity and can compete with the cell-surface receptor for Ig binding. Most obviously, perhaps, FcRs can behave as vehicles for mediating uptake of antibody-coated pathogens leading to intracellular destruction of the organisms, although FcRs can also be linked to exocytotic responses that allow cells rapidly to release pharmacological mediators and/or toxic proteins toward a pathogen in a tightly focused manner. Finally, FcRs perform regulatory roles in ongoing immune responses, serving to maintain overall homeostatic control of humoral responses to pathogens.

Receptors for IgG

There are three main subsets of receptors specific for the Fc region of IgG molecules (FcγR), each with distinctive subclass-binding preferences and tissue distributions. Each FcγR type exists in several isoforms, being encoded by separate individual genes located at chromosome 1q and/or by alternate splice variants of those structural genes. All FcγR species belong to the Ig-like domain superfamily and possess two or three extracellular Ig-like domains.

Table 4 *Properties of human Fc receptors*

Ig bound	Receptor	CD	Gene	Chromosome	Transcripts	Proteins (kDa)	K_d (l/mol)	Isotype preference	Signaling	Complex
IgM	Fcα/μR			1q32.3		70	3×10^9 (IgM), 3×10^8 (IgA)	IgM > IgA		
IgD	FcδR					70				
IgG	FcγRI	CD64	FcγRIA	1q21	FcγRIa	60–70	10^8–10^9	3 > 1 > 4 >> 2	γ	$\alpha\ \gamma_2$

					FcϵRIIb	45	10^7			
IgM, IgA	pIgR					100–105	2×10^9 (IgM), 10^8 (IgA)	IgM > IgA		

ITAM, immunoreceptor tyrosine-based activation motif; ITIM, immunoreceptor tyrosine-based inhibitory motif; pIgR, polymeric Ig receptor.

FcγRI (CD64)

FcγRI (CD64) is the high-affinity IgG receptor, capable of binding monomeric IgG molecules. There are three structural genes encoding FcγRI (CD64), FcγRIA, -B, and -C (Ernst et al. 1992). These genes give rise to primary protein products of 30–40 kDa which are subsequently heavily glycosylated to yield mature glycoproteins of about 60–70 kDa (Ernst et al. 1998). The FcγRIA and -C genes each gives rise to a single transcript and protein product, named FcγRIa and FcγRIc, respectively, whereas the FcγRIB gene directs the synthesis of two RNA and protein products, FcγRIb1 and FcγRIb2 (Ernst et al. 1998). The FcγRIa membrane protein has three extracellular V-like Ig domains (EC1–3), whereas the FcγRIb and FcγRIc proteins possess only two such domains and lack the EC3 domain. FcγRI is the sole member of this family that is capable of binding monomeric IgG molecules, and is regarded as the high-affinity IgG receptor (association constant K_a roughly 10^8–10^9/mol per l) (Allen and Seed 1989; Shopes et al. 1990). FcγRI binds monomeric IgG1, -3, and -4 subclasses, with a preference for IgG3 and IgG1 molecules, but binds IgG2 only very weakly.

FcγRI molecules are type I integral membrane glycoproteins anchored to the cell surface via a single transmembrane helix, and they possess a large intracellular domain (Allen and Seed 1989). However, there are no signaling motifs found in this domain and the FcγRI molecule must associate noncovalently with a disulfide-bonded dimer of the γ chain of the high-affinity IgE receptor, in order to trigger intracellular signaling pathways in FcγRI$^+$ cells (Ernst et al. 1993; Scholl and Geha 1993). The γ chains possess immunoreceptor tyrosine-based activation motifs (ITAM) that recruit the necessary protein tyrosine kinases for initiation of intracellular signaling following receptor cross-linking (see The B cell antigen receptor). The stoichiometry of the FcγRI receptor complex is $\alpha\gamma_2$. The presence of an ITAM within the FcγRI complex allows this FcγR to function as an 'activating' receptor on monocytes/macrophages, granulocytes, natural killer (NK) cells, platelets, and certain lymphocyte subsets. Interaction of these receptors with IgG activates phagocytosis and uptake of the immune complex (or opsonized target), secretion of inflammatory mediators (cytokines and lipid mediators), and release of other toxic agents required to bring about ADCC. Alterations to patterns of gene expression in activated cells also occur. The principal functions of FcγRI are in uptake of immune complexes, delivery of ADCC to opsonized target, initiation of inflammatory responses, and, in an immunoregulatory context, delivery of antigen in immune complexes into processing pathways for subsequent presentation to T cells.

The binding site on IgG is located in the Cγ2 domain and the lower hinge region of IgG also contributes to FcγRI–IgG interaction. The capacity of IgG to interact with the high-affinity monocyte FcR is a particular property of the Cγ2 domain of the molecule (Woof et al. 1986) and Leu235 in the Cγ2 domain is critical in the interaction (Duncan et al. 1988). As with the IgG–Clq interaction, the carbohydrate groups seem to be necessary for optimal receptor–ligand interaction, because absence of oligosaccharides severely reduces binding of IgG to FcR; the precise molecular role of the oligosaccharides is not well understood. Binding of monomeric IgG to the receptor drives internalization, but the FcγRI-IgG complexes are recycled to the plasma membrane. It is only when FcγRI molecules are cross-linked that the internalized complexes are targeted to intracellular vesicles involved in protein hydrolysis or oxidative killing of organisms (Harrison et al. 1994). The FcγRI–IgG interaction follows a 1:1 stoichiometry.

FcγRII (CD32)

As with the FcγRI family, three independent structural genes at chromosome 1q23-24 encode FcγRII transcripts and proteins (Ernst et al. 1992). The FcγRIIA gene encodes two transcripts (FcγRIIa1 and FcγRIIa2), the FcγRIIB gene three transcripts, whereas the FcγRIIC gene yields only a single transcript (Dijstelbloem et al. 2001). The FcγRII family bind monomeric IgG with relatively low affinity (K_a roughly 10^7/mol per l) and so are unlikely to bind IgG in a monomeric form (Hulett and Hogarth 1994). The mature cell surface receptor glycoproteins have M_r values in the 35 000–41 000 range, with a single transmembrane helix. All isoforms possess two Ig-like extracellular domains and, in striking contrast to FcγRI (and FcγRIII) proteins, the cytoplasmic domains of FcγRII proteins contain ITAM or tyrosine-based inhibitory (ITIM) motifs that allow these receptors to link to intracellular signaling cascades without the need for association with other membrane proteins (Daeron 1995; Van den Herik-Oudijk et al. 1995). The FcγRII proteins display subtle differences in IgG subclass-binding specificity, but there is a general preference for IgG3 and, to a lesser extent, IgG1, with binding of IgG2 and IgG4 being of much lower affinity (Dijstelbloem et al. 2001). As with FcγRI, the binding site on IgG involves the Cγ2 and lower hinge regions of IgG, with residues 234–237 being important for the interaction.

Each FcγRII protein type displays a characteristic pattern of expression. FcγRIIa is expressed at good levels on monocytes and macrophages, and on neutrophils, but is essentially absent from NK cells and lymphoid cells. FcγRIIb proteins are found on monocytes and macrophages, but not on neutrophils, NK cells, or T cells. FcγRIIb is, however, expressed on both B lymphocytes and follicular dendritic cells, where it has key roles in positive and negative regulation of B-cell responses.

FcγRIII (CD16)

The two highly homologous FcγRIII genes are also found at chromosome 1q23-24, and encode mature proteins of quite different character; there are no reports of alternate transcripts from either of the FcγRIIIA or FcγRIIIB genes (Ravetch and Perussia 1989). Both protein products have external regions of about 180 amino acids arranged as two Ig-like domains, have a low to medium affinity for monomeric IgG (K_a roughly 1–3 $\times$ 10^7/mol per l) and so are likely to bind IgG only in immune complexes or aggregates (Ghirlando et al. 1995). As with other FcγRs, there is a preference for binding of IgG3 and IgG1 subclasses over the IgG2 and IgG4 isotypes. Receptor–ligand complexes show a 1:1 stoichiometry (Ghirlando et al. 1995), and the target region of IgG for binding of FcγRIII is as described for FcγRI and FcγRII.

The FcγRIIIa protein is a heavily glycosylated transmembrane glycoprotein, containing two extracellular Ig-like domains and a small cytoplasmic domain that lacks ITAM and/or ITIM motifs (Ravetch and Perussia 1989); FcγRIIIa must, therefore, associate with other chains possessing such motifs to gain signaling capability. This is provided either by the γ chain of the high-affinity IgE receptor (Hibbs et al. 1989), as is observed with FcγRI, or by the ζ chain of the CD3–TcR complex (in NK cells – Lanier et al. 1989). FcγRIIIa is expressed on neutrophils and eosinophils and also by NK cells; activated macrophages in the tissues are also FcγRIIIa$^+$, although the receptor is absent from monocytes in the peripheral circulation. FcγRIIIB, by contrast, encodes a smaller protein product, FcγRIIIb, which is associated with the plasma membrane via a glycophosphatidylinositol (GPI) linkage (Ravetch and Perussia 1989), a feature that mandates both a lack of a cytoplasmic domain and ease of release from the membrane via the action of phospholipases. FcγRIIIb is expressed principally by neutrophils, but its expression is also induced in eosinophils by IFNγ.

Neonatal FcRn

A final group of receptors for IgG found on endothelial and epithelial cells in some tissues are the 'neonatal FcR' class (FcRn), so called in recognition of their discovery in intestinal epithelial cells of neonatal rats (Jones and Waldmann 1972). These receptors also possess Ig-like domains, but are strikingly structurally related to MHC class I molecules. The functions of FcRn include transport of IgG from the gut lumen to the bloodstream, transfer of maternal IgG across the placental barrier to the neonatal circulation, and possibly maintenance of overall levels of IgG in the circulation. Uniquely among Fc receptors, the FcRn molecules bind ligand as a homodimeric receptor and show a notable pH dependence for ligand binding.

FcRn

FcRn is a noncovalent heterodimeric complex comprising the FcRn α chain (Simister and Mostov 1989a, b), a type I transmembrane glycoprotein, and the peripheral membrane protein β_2-microglobulin (Simister and Rees 1985). The organization and structural features of FcRn are therefore very similar to those of a class I MHC antigen. The FcRn α chain is 45–50 kDa and has three external domains – α1, α2, and α3 – with the last, most proximal membrane being a classic C-region type Ig domain (Simister and Mostov 1989a, b). The α1 and α2 domains have four β strands and a long α-helical region, highly reminiscent of the peptide-binding grooves of MHC antigens, but the α helices in FcRn are very close together and this precludes formation of a 'groove-like' structure (Raghavan et al. 1993; Burmeister et al. 1994a).

FcRn has an intermediate affinity for monomeric IgG (K_a roughly 2–5 $\times$ 10^7/mol per l) (Wallace and Rees 1980; Raghavan et al. 1995) and, unlike other FcγR species, appears to function as a homodimer with a receptor–IgG binding stoichiometry of 2:1. Surface plasmon resonance studies indicate that FcRn monomers have a 100-fold reduced affinity for IgG compared with FcRn dimers (Raghavan et al. 1995). The FcRn dimers are formed via contacts between the α3 and β_2-microglobulin domains and it is believed that dimer formation is dependent on binding of IgG (in a manner similar to that observed in, for example, the growth hormone–growth hormone receptor interaction). Crystallization studies suggest that the FcRn dimer adopts an unusual configuration in its asymmetrical binding of IgG molecules (Burmeister et al. 1994a, 1994b). Thus, receptor contacts with IgG were at the interface of the Cγ2 and Cγ3 domains and were made by only one of the two FcRn molecules in the complex via residues at the edge of the α1/α2 domains and the amino-terminal region of β_2-microglobulin (Burmeister et al. 1994b). The region bound by FcRn is distinct from that bound by other FcγR species and is more akin to that bound by, for example, protein A from the Cowan I strain of *Staphylococcus aureus* (Deisenhofer 1981). The contacts between FcRn and the Cγ2 and Cγ3 interface region involve conserved histidine residues in both partners (His250 and -251 in FcRn and His310 and -433 in IgG) (Burmeister et al. 1994b). The model further suggested that, in order to bind IgG, the dimer of the FcRn molecule would be positioned such that its long axis lay parallel to the plane of the plasma membrane. In this model, the FcRn dimer is 'lying down' in order to capture ligand, and this contrasts with the 'standing up' orientation of class I MHC molecules (and indeed many other FcγR species) where the ligand-binding site projects away from the membrane distal end of the molecule (Burmeister et al. 1994b). Robust evidence that Fc receptors can adopt 'lying down' configurations is provided by the

X-ray crystallographic analysis of the FcεRI–IgE Fc interaction (see 'The interaction of IgE with soluble FcεRIα', below).

FcRn molecules are found in intestinal epithelial cells (Jones and Waldmann 1972), the yolk sac in mice (Ahouse et al. 1993), certain subsets of hepatocytes (at least in rats), and human placenta (Story et al. 1994). FcRn has an intermediate affinity for IgG, but shows a pronounced pH dependence in ligand binding. Binding is optimal and stable at pH 5–6, but is reduced up to 100-fold as pH increases beyond neutrality (Story et al. 1994). This ensures that IgG is bound at the apical (or luminal) surface of intraepithelial lymphocytes (IEL) in the gut where the pH is low, moved across the cell by transcytosis and released by the receptor at the basolateral surface of the cell (blood side) where the pH is neutral. However, there is no pH gradient across the placental barrier and, in this instance, it is proposed that IgG is bound by FcRn in intracellular acidic vesicles which are subsequently targeted to the basolateral face of the cell for release into the fetal circulation (Story et al. 1994). FcγRII is thought to be responsible for the initial binding and uptake of IgG on placental cells and delivery of the IgG to the appropriate intracellular vesicles for interaction with FcRn. The pH sensitivity of FcRn function is explained by the presence of histidine residues in the region of contact between the receptor and IgG. Once IgG is released, the FcRn dimer dissociates and is re-cycled for further rounds of transcytotic delivery of IgG, a situation that contrasts with IgA transport via the polymeric Ig receptor (see 'The polymeric immunoglobulin receptor' below).

IgE receptors

IgE is found at low levels in the blood in normal individuals and, functionally, is responsible for initiating powerful local (and sometimes systemic) acute inflammatory responses (Metzger 1994, 1999; Sutton and Gould 1993). There are two receptors for IgE distinguished by profoundly different structures, cellular functions, tissue distribution, and, importantly, affinities for IgE. The effects of IgE-mediated allergic reactions are almost entirely explained by the biology of the high-affinity IgE receptor, and it is fair to note that the efforts to understand the structure and function of this receptor have driven forward our understanding of receptors for other Ig isotypes.

FcεRI

FcεRI is the high-affinity receptor for IgE, and is a tetrameric complex of three transmembrane glycoprotein chains (Blank et al. 1989): the α chain, responsible for IgE binding, the β chain, and a dimer of the γ chain which is responsible for activation of intracellular signaling via its ITAM motifs. The affinity of FcεRI for IgE is sufficiently high (K_a roughly 10^{10}/mol per l) to dictate that monomeric IgE is bound by the receptor (Beavil et al. 1993); this partly explains the observation that serum IgE levels are low because, in fact, most of the IgE is essentially irreversibly bound to FcεRI$^+$ cells. FcεRI is expressed on mast cells, basophils, and eosinophils, where crosslinking of receptors leads to an exocytotic response, and also on dendritic and monocytic cells where a role in antigen processing and presentation is more likely.

The FcεRI α chain possesses two extracellular Ig-like domains: a transmembrane region and modest cytoplasmic domain of about 25 residues (Kinet et al. 1987). The cytoplasmic domain lacks signaling motifs, but linkage to signaling pathways is provided via the ITAM motifs found in the β and γ chains of the receptor complex (Nadler et al. 2000). The β chain belongs to the tetraspanin family of membrane proteins, passing through the membrane four times, and both the amino and carboxyl termini of the β chain are exposed in the cytoplasm (Kinet et al. 1988). The carboxy-terminal cytoplasmic domain contains an ITAM motif. The γ chain possesses a small extracellular domain, a transmembrane region, and a large cytoplasmic domain that contains ITAM motifs. The dominant FcεRI stoichiometry found on mast cells and basophils is $\alpha\beta\gamma_2$, but other cell types where the IgE receptor may be involved in antigen processing rather than exocytosis (e.g. monocytic cells) show a different FcεRI stoichiometry of $\alpha_{2\gamma}$.

FcεRII (CD23)

FcεRII is the low-affinity receptor for IgE, and is expressed on a range of cells of hemopoietic origin (Delespesse et al. 1992; Bonnefoy et al. 1997). It is a 45-kDa type II transmembrane glycoprotein and is expressed as a noncovalent homotrimeric assembly at the plasma membrane. The affinity for IgE is significantly lower than that of FcεRI (K_a roughly 10^7/mol per l) (Sutton and Gould 1993). FcεRII is encoded by a single gene at chromosome 19p21 (Soilleux et al. 2000) that gives rise to two isoforms – FcεRIIa and FcεRIIb (Yokota et al. 1988) – that differ by six or seven residues at their cytoplasmic amino terminus, and are proposed to be linked to distinct signaling and uptake pathways (Yokota et al. 1992). In human B cells, the two isoforms are subject to distinct patterns of transcriptional regulation (Ewart et al. 2002). FcεRII is unusual among the Fc receptors in that it is not a member of the Ig superfamily, but rather has features that suggest that it is a member of the calcium-dependent family of C-type animal lectins (Delespesse et al. 1992; Bonnefoy et al. 1997). The membrane form of FcεRII/CD23 can be released as several soluble proteins (soluble CD23 or sCD23) and these can act as cytokine-like molecules (Gordon et al. 1989), influencing IgE synthesis and apoptosis in mature B cells (Liu et al. 1991a; Flores-

Romo et al. 1993) and pre-B cells (White et al. 1997), and proinflammatory cytokine synthesis in monocytic cells (Lecoanet-Henchoz et al. 1995; Hermann et al. 1999). The findings of two FcεRII isoforms and cytokine-like activities of sCD23 are apparently unique features of the human FcεRII proteins.

The binding site for FcεRII on IgE is, like that for FcεRI, located in the Cε3 domain of IgE. The precise location of the contact sites for FcεRII is not precisely defined. Soluble CD23 molecules can bind IgE and compete with FcεRI for IgE binding, via simple steric hindrance, thereby providing a degree of antagonism for loading of mast cell FcεRI with IgE. In this context, it is unsurprising that atopic individuals not only have high serum IgE levels, but also have elevated concentrations of sCD23 in their serum (Yanagihara et al. 1990; Wilhelm et al. 1994). FcεRII molecules can bind IgE and on crosslinking can rapidly take up the FcεRII–IgE immune complexes, and FcεRII is required for IgE-dependent antigen processing and presentation. Ligation of FcεRII with IgE–allergen complexes delivers a negative regulatory signal to B cells, downregulating production of IgE (Luo et al. 1991). Mice lacking FcεRII fail to show a negative regulation of IgE antibody responses (Yu et al. 1994). The structural basis for FcεRII function remains to be elucidated.

IgA receptors

IgA is the most abundant Ig class in the body, having a relatively short half-life coupled with a high synthetic rate. IgA functions in several tissue compartments, namely the blood, gut, and airways, and requires receptors both for performance of effector functions and for transport from sites of synthesis to secretory surfaces. IgA therefore interacts with the polymeric Ig receptor (discussed in detail below), an IgM receptor that has specificity for both IgM and IgA (see under IgM receptors), and also with an IgA-specific receptor that assists in the protective functions of IgA. There are also data to suggest that the transferrin receptor can act as a receptor for IgA1 (Moura et al. 2001).

FcαRI (CD89)

FcαRI is an IgA-specific receptor expressed on monocytic cells, neutrophils, and eosinophils (van Egmond et al. 2001). The receptor is a complex comprising the CD89 molecule (the receptor α chain), a transmembrane glycoprotein comprising two Ig-like extracellular domains, a transmembrane helix, and a small cytoplasmic domain (Maliszewski et al. 1990), in noncovalent association with a dimer of the γ chain found in FcεRI, FcγRI, and FcγRIIIa complexes (van Egmond et al. 1999). CD89 is encoded on chromosome 19 (Martin et al. 2002). As in the other receptors, it is the γ chain that is responsible for initiation of signaling in cells following activation of the IgA receptor. The affinity (K_a roughly 10^6/mol per l) is relatively low (Wines et al. 1999), suggesting that IgA will bind to the receptor only in complexes or aggregates rather than in a monomeric form. Both IgA subclasses are bound equally well by FcαRI, a result consistent with the mapping of the binding site, on IgA itself, to the interface between the Cα2 and Cα3 domains (Pleass et al. 1999).

IgA is classically considered to be a 'non'-inflammatory immunoglobulin isotype. However, given the pattern of expression of FcαRI, it is difficult to envisage how FcαRI and FcγRI, both using the γ chain as signal initiator, would generate anti- and proinflammatory responses, respectively, after activation. It is therefore unsurprising that $Fc\alpha RI^+$ neutrophils can both phagocytose IgA-coated particles (Weisbart et al. 1988) and generate a subsequent powerful oxidative burst (Keler et al. 2000). $Fc\alpha RI^+$ cells can also mediate ADCC-type lysis of tumor cells (Keler et al. 2000), and FcαRI is important in IgA-dependent antigen processing and presentation (Geissmann et al. 2001). The FcαRI complex should therefore be regarded as an 'activatory' FcR in the same way as FcγRI, although FcαRI may act as an overtly proinflammatory receptor in a more limited set of circumstances.

IgM receptors

IgM is the first Ig isotype to be produced in an immune response, and levels of IgM are known to be important in feedback homeostatic regulation of antibody responses. This observation suggests that receptors for IgM are expressed on a range of cell types. There are two main types of IgM receptor, a GPI-linked IgM-binding protein found in activated human B cells and a receptor, Fcα/μR, that binds both IgM and IgA, but is distinct from CD89/FcαRI and, with the exception of a small conserved motif, from pIgR.

Fcα/μR

Fcα/μR is a transmembrane glycoprotein of 535 amino acids, encoded by a gene located at chromosome 1q32.3, with no significant homology to proteins already recorded in public databases, apart from single Ig-like domain in the extracellular region (Shibuya et al. 2000). The protein is heavily glycosylated and has a molecular mass of about 70 kDa. The Ig-like domain of Fcα/μR has a stretch of some 25 residues that shows strong conservation with the polymeric Ig-binding site found in the most membrane distal Ig-like domain of the poly-Ig receptor (pIgR). This site is regarded as a potential binding site on Fcα/μR for IgM and IgA. Overall, however, Fcα/μR has less than 10 percent homology to pIgR.

The Fcα/μR molecule binds IgM with high affinity (K_a roughly 3×10^9/mol per l), and the murine receptor can bind mouse, human and rat IgM molecules with broadly

similar affinity. Fcα/μR also binds IgA, but with a lower, intermediate affinity (K_a roughly 3×10^8/mol per l). The receptor is capable of mediating endocytic uptake of IgM-coated particles, raising the possibility that this receptor could deliver antigen in IgM immune complexes to the antigen-processing machinery of the cell. It remains unclear whether ligation of Fcα/μR on monocytic cells leads to proinflammatory cytokine synthesis, and whether IgA-coated targets can be internalized by Fcα/μR$^+$ cells (Shibuya et al. 2000). The cytoplasmic domain contains no ITAM/ITIM motifs and it is reasonable to expect that Fcα/μR will associate with other membrane proteins in order to activate intracellular signaling pathways in the cells expressing it. However, there are no data to suggest that Fcα/μR associates with the γ chain found in other FcR complexes. In hemopoietic tissue, the receptor is expressed in B cells, including B-cell precursors, and on macrophages, but is absent from granulocytes, T lymphocytes, and NK cells. In nonlymphoid tissue, Fcα/μR transcripts are detected in liver, kidney, intestinal tissue, testis, and placenta, and also on thymic stroma (Shibuya et al. 2000). The functions of Fcα/μR in these tissues remain to be fully characterized.

IgD receptors

Although the existence of IgD receptors (IgD-R) is well documented, the formal molecular characterization of these binding proteins has proved a difficult problem (Preud'homme et al. 2000). The receptors expressed on human T cells appear to bind both membrane-associated IgD and secreted IgD and, in the case of the latter type, monomeric and polymeric (i.e. complexed or aggregated) forms (Coico et al. 1988b). Thus, monomeric IgD tends to downregulate IgD-R expression, whereas higher oligomers tend to enhance its expression (Coico et al. 1987, 1988a). The molecular mass of the receptor is about 70 kDa in human cells (the murine receptor appears to be different, containing two components), but there are no details of its primary or higher structural features (Tamma and Coico 1992). The receptor species appear to bind to O-linked oligosaccharides of the IgD molecule, a feature that accounts for the ability of IgD-R also to bind IgA1 molecules (Swenson et al. 1998). In the murine system the interaction of IgD-R with Ig requires Ca^{2+}, suggesting a C-type lectin interaction (Swenson et al. 1993). The paucity of molecular details makes difficult the task of defining functions for IgD-R. However, it is likely that the main roles of this receptor are in the antigen presentation process. The observation that monomeric IgD can drive IgD-R downregulation suggests that the receptor protein or complex has at least intermediate affinity for IgD, otherwise monomeric IgD would not bind for a sufficient time to be internalized. If the IgD-R is endocytosed, as seems likely in light of the trafficking of other receptors, crosslinked receptors may be internalized and routed to processing compartments for assembly of peptides into MHC molecules. Other data suggest that IgD-R can interact with glycans on membrane IgD on B cells and so enhance cell–cell contact between T cells and B cells. The molecular basis for all the potential functions of IgD-R requires cloning of receptor complementary DNAs (cDNA).

The polymeric immunoglobulin receptor

The secretory surfaces of the gut and airways are protected by secretory IgA (sIgA) (Johansen et al. 2000) or, in the case of individuals with selective IgA deficiencies, secretory IgM (sIgM) (Thompson 1970). In each case, the newly synthesized Ig must be transported from the site of synthesis across a cellular barrier in order to reach the tissue space where its protective function can be expressed. This transport is achieved via transcytosis and is mediated by the pIgR. In this elegant process, the pIgR collects the polymeric Ig at the basolateral surface of the cell, transports it via the cell cytoplasm to the apical surface, and is then itself cleaved and released from the cell (Mostov et al. 1984; Johansen et al. 2000). The cleaved pIgR molecule remains bound to sIgA (-M) as secretory component (SC) and now offers a degree of protection against proteolysis in the airway or gut microenvironment.

pIgR

Like most other Ig-binding proteins, pIgR is a member of the Ig-domain superfamily. The mature pIgR has a molecular mass of 100–105 kDa, and contains five Ig-like domains in the extracellular region of the receptor (named D1–D5), a transmembrane helix, and a cytoplasmic domain (Mostov et al. 1984). The five extracellular domains are very similar to V-like Ig domains (Mostov et al. 1984), and the cytoplasmic domain contains a targeting motif that ensures targeting of pIgR to the basolateral surface of the cell after biosynthesis (Casanova et al. 1991). There are separate motifs that facilitate rapid endocytosis after binding of pIgR and inhibition of unwanted delivery of the endocytosed complex to lysosomal compartments during transcytosis. The D1 domain is the main site of binding of polymeric Ig, although the remaining extracellular domains also contribute to binding. Pentameric IgM and dimeric IgA bind to pIgR in different ways, and association constants for the interaction of pIgR with each isotype are distinct (K_a roughly 2×10^9/mol per l for IgM (Goto and Aki 1984) and roughly 10^8/mol per l for IgA (Kuhn and Kraehenbuhl 1979)). Possession of J chain within the polymeric Ig appears to be a requirement for interaction with pIgR. Polymeric, J-chain-containing IgA molecules

bind pIgR via D1 (Coyne et al. 1994), but also appear to require contacts between the α chain and the D2 and D3 domains of pIgR for stable receptor interaction (Norderhaug et al. 1999). A disulfide bond is formed between Cys467 in pIgR and Cys311 in the Cα2 domain of the IgA molecule (Fallgreen-Gebauer et al. 1993), which gives further stability to the complex. In contrast, binding of IgM to the pIgR appears to require only the D1 domain (Roe et al. 1999); there appears to be no need for contacts between the μ chain and D2/D3 domains, nor is a μ chain–pIgR disulfide bond formed (Fallgreen-Gebauer et al. 1993). The site of interaction of IgA α chains with pIgR appears to map to the Cα3 domain, with Cα2 also likely to be involved (Geneste et al. 1986).

Although it is indisputable that J chain is required for interaction of polymeric Igs with pIgR, what is less definitively clear is whether J chain itself makes direct physical contact with pIgR (Johansen et al. 2000). Data from knock-out mice lacking either J chain (Hendrickson et al. 1995) or pIgR (Johansen et al. 1999), in which both strains fail to transport Ig, argue in favor of a direct interaction. The capacity of anti-J-chain antibodies to block the interaction of polymeric IgA and pIgR are also consistent with a direct interaction between pIgR and J chain (Brandtzaeg 1975). However, phage display experiments demonstrating a strong interaction between Cα3 peptides and pIgR argue against a mandatory requirement for J chain for the interaction of polymeric Igs with pIgR (Hexham et al. 1999). The precise role of J chain remains to be defined, but it is possible that it interacts with polymeric Ig to create a conformation that can be bound effectively by pIgR.

STRUCTURAL BIOLOGY OF IMMUNOGLOBULINS AND IMMUNOGLOBULIN RECEPTORS

Elucidation of protein structure via X-ray crystallographic analysis invariably provides great insights into the molecular basis of protein function. The structures provide significant insight into the functions of Ig molecules and their receptors.

Structure of human IgG1: the b12 anti-HIV-gp120 MAb

The b12 human IgG1κ antibody was isolated from a phage-display combinatorial library prepared from bone marrow cells derived from an HIV-positive donor. The antibody recognizes an epitope on the gp120 protein that partially overlaps the site recognized by CD4, and the MAb can neutralize HIV infectivity by many strains both in vitro and in in vivo animal models (Burton et al. 1994).

The b12 IgG1κ molecule is highly asymmetrical in shape and structure (Saphire et al. 2001a,b). The molecule as a whole lies somewhere between a 'T' or 'Y' shape, but the Fc region does not lie centrally beneath the Fab arms. Rather, it is shifted significantly to one side of the central axis of symmetry of a Y-shaped IgG molecule and lies largely under only one of the Fab arms (Figure 5). Thus, one Fab arm sits on top of the Fc region and can make physical contact with it (via Cγ2), whereas the second Fab arm makes no contact at all with the Fc domains. In detailed terms (Saphire et al. 2001a, 2001b), the Fab arms lie at an angle of 143–148° relative to each other with a distance between the two apices of the combining sites on the Fab arms of 17.1 nm. The Fc region is offset by 3.2 nm from the central axis of the molecule and is twisted by almost 90° relative to the major axes of the Fab arms. The Fab arms are also rotated relative to each other, such that the light chains appear on opposite sides of the heavy chain in the intact molecule. The V_H–V_L and CH_1–C_L domains in the Fab arms have a unique 'elbow' angle between their individual axes of symmetry.

In the Fc region, the two Cγ3 domains pack closely with essentially complete symmetry, whereas the Cγ2 domains make few protein–protein contacts as a result of the presence of the N-linked oligosaccharides in the space between the domains. The Fc region can show rotational and translation shifts relative to the Fab arms, meaning that different angles exist between this region and the two Fab arms. This has consequences for the disposition of the hinge region where the hinge angle in a single molecule can be quite different. In the case of the b12 IgG1κ molecule, one hinge angle is acute (66°) and the other obtuse (113°) (see Figure 5).

The b12 molecule allowed good visualization of the hinge region in an intact human IgG molecule (Saphire et al. 2001a, b). The 17-residue hinge of IgG1 molecules is functionally split into three regions: an upper hinge close to the Cγ1 domain, a core hinge, and a lower hinge immediately proximal to the Cγ2 domain. The upper hinge allows rotation and other movement of the Fab arm, and the lower hinge serves the same function relative to the Fc region; the core hinge is cysteine and proline rich and is therefore involved in interchain disulfide bridging between the γ heavy chains. Surprisingly, however, the crystal structure of IgG1κ reveals that only one of the two possible disulfide bonds in the hinge region actually forms; the Cys226 residues form a disulfide, but the Cys229 residues do not. In general terms, the b12 hinge region appears to have an extended conformation, with the upper and lower hinges being somewhat disordered in the crystal structure and the core hinge having some polyproline helical character.

The combining site structure of the b12 molecule departs from the conventional view of a large flat area available for surface-to-surface contacts between the antibody and the protein antigen. The b12-combining site could be considered as a large 'spike' flanked by two platforms. The spike region is contributed by the long

CD3 of the heavy chain (CDR H3), and one platform of 1.1 nm width is composed of the remaining two heavy chain CDRs and the second platform of 0.7 nm width by the three light chain CDRs. The CDR H3 is longer than normal, a feature common to anti-CD4 neutralizing antibodies and, in the combining site, protrudes 1.5 nm above the plane of the low, light chain 'platform' and is tipped by Trp100 (Saphire et al. 2001b). In complex with the gp120 monomer, 103 nm of gp130 and 104 nm of the b12-combining site are buried, and the intercalating residues on the two proteins are completely complementary. In particular, the Trp100 residue of CDR H3 of the b12 antibody protrudes precisely into the same pocket that would be occupied by a critical residue of CD4 (Phe43) – a feature that helps to explain the capacity of b12 to act as a potent neutralizing antibody.

The availability of the b12 structure allows comparisons to be made with other complete structures (e.g. of murine IgG2a and IgG1 molecules) or partial structures (Saphire et al. 2002). The human structure differs profoundly, but a common feature is the extent of asymmetry in the structures. Thus, although the primary structures of the two 'halves' of the IgG molecules are identical, they have completely different structures. In terms of general layout, murine IgG1 is more Y-shaped, with the angle between the Fab arms being 115°, whereas the murine IgG2a has a more T-like organization with an angle of 172° between the Fab arms. The Fab 'elbow' angles in murine IgG1 appear to be identical, whereas the IgG2a equivalents are slightly different (143° and 159°). Significant differences also exist in the position of the Fc region relative to the Fab arms. Thus, in b12, the Fc region is twisted and offset by 3.2 nm relative to the plane of the Fab arms, whereas murine IgG2a is shifted 2.6 nm and away from both Fab arms such that essentially no contact between the Fc and Fab arms takes place. The Fc 'elbow' angles of the murine IgG1 and IgG2a molecules are in close agreement with the b12 Fc elbow angle, being 177.2° and 176.6°, respectively. The hinges of murine IgG1 (19 residues) and IgG2a (12 residues) are broadly similar to the b12 structures, showing extended conformations with different torsion angles in the two heavy chains. However, in contrast to b12, all three possible interchain disulfide bridges in both murine Ig hinges are formed (Saphire et al. 2002).

Structure of the IgE Fc region

Biophysical studies clearly indicate that the IgE molecule in solution is 'bent' in conformation such that the distance between the tips of the Fab arms and the tail of the Fc region is approximately 7.5 nm (see Figure 5), in both free and receptor-bound forms (Zheng et al. 1991, 1992). Recent success in crystallizing the Fc region (Cε2–Cε4) of human IgE provides insight into the structural basis for IgE 'bending' and begins to explain the asymmetry of the interaction of IgE with its high-affinity receptor (Wurzburg et al. 2000; Wan et al. 2002; Wurzburg and Jardetzky 2002).

The IgE Fc region contains three C-type Ig domains and has no hinge region, with the Cε2 domain occupying this position in the IgE molecule. The Cε3 and Cε4 domains can be regarded as broadly similar to the Cγ2 and Cγ3 domains of IgG, with Cε4 domains being essentially symmetrical and making extensive protein–protein contacts, and the Cε3 domains being held apart in space by oligosaccharide groups. In crystals of the Cε3/Cε4 protein (Wurzburg et al. 2000), the Fc region adopts a relatively 'closed' configuration relative to IgG Fc, but this structure 'opens up' somewhat upon interaction with the FcεRI, with the two Cε3 domains moving 1 nm apart (Wurzburg et al. 2000; Garman et al. 2000). The IgE Fc also shows considerably greater flexibility than that described for IgG Fc regions (Wurzburg et al. 2000).

However, it is in the Cε2/Cε4 Fc structure, where a pronounced bend occurs at the region that links the Cε2 domains to Cε3, that the most striking feature of the IgE Fc is found (Wan et al. 2002). The Cε2 domains associate with a high level of symmetry, adopt classic Ig-like folding patterns, but unusually use polar contacts (rather than nonpolar) to stabilize the domain interaction. The linker region between Cε2 and Cε3 is dramatically bent, folding acutely through 62° and back onto the Cε3 and Cε4 domains (Wan et al. 2002) (see Figure 5). A consequence of this acute folding back is that the Cε2 domain of one ε chain makes extensive contacts with both the Cε3 and Cε4 domains of the second ε heavy chain, whereas the second Cε2 domain makes rather few contacts with the more carboxy-terminal domains. The contacts made between Cε2 and the Cε3/4 region are therefore highly asymmetrical. The interaction buries a total 39.0 nm^2 of solvent-exposed surface on the Cε2/Cε4 molecule (30.6 nm^2 on Cε3 and 24.1 nm^2 on Cε4, respectively) and a total of six hydrogen bonds and three salt bridges are formed. Experiments with purified Cε2 and Cε3/Cε4 proteins in vitro suggest that the affinity of interaction between these domains is in the micromolar range, a value consistent with the area of surface interaction. A final notable feature of the asymmetry of the IgE Fc region relates to the two disulfide bridges in the Cε2 domains. These disulfides are formed by Cys241 and Cys328 in the ε heavy chain, but, rather than forming 'parallel' bonds, the disulfides 'crossover' in the structure, i.e. in each case, Cys241 interacts with Cys328 to form the disulfide bond (Wan et al. 2002).

The interaction of IgE Fc with soluble FcεRIα

The recent crystallization of a soluble FcεRI α chain–IgE Fc complex reveals the basis for IgE binding to the

receptor (Garman et al. 2000). The complex stoichiometry is 1:1, there is no role for carbohydrate groups on either IgE or the receptor in the interaction, and there is little change in the receptor after ligand binding. Contacts are made exclusively between the Cε3 domain and the α chain; although the Cε4 domain provides a dimerization platform for IgE Fc, neither this domain itself nor the Cε3/Cε4 interface region makes physical contact with the receptor. The Cε3 domain binds at two distinct sites on the receptor, the first site being along one edge of the D2 domain, and the second being located at the apex of the interface between the D1 and D2 regions (Garman et al. 2000). These data explain earlier studies which suggested that mutant α chains lacking the D1 domain still bound IgE but with vastly reduced affinity; both sites are needed for high-affinity binding. The binding site along the edge of the D2 domain is centered around tyr131, while site two involves four tryptophan residues located some distance apart in the primary sequence (Trp87, Trp110, Trp113, and Trp156).

IgE adopts an unusual 'bent' conformation in solution, and retains this when bound to FcεRI (Zheng et al. 1991, 1992). The bending of IgE results in the molecule presenting a convex and a concave face, with only the convex face presenting a functional binding site for the FcεRI complex. This explains the observed FcεRI–IgE stoichiometry of 1:1. The data suggest that the FcεRI complex adopts a 'lying-down' conformation on the cell surface such that the Cε2–Cε3 interface region is readily available for interaction with the bent IgE ligand (Garman et al. 2000).

The interaction of IgG Fc with soluble FcγRIII

The molecular basis of the interaction of the Fc region of IgG with an Fc receptor was visualized using a soluble, two-domain form of the FcγRIII molecule (Sondermann et al. 2000). The partners interact with a K_a of roughly 5×10^5/mol per l, which is lower than found with intact proteins. The data obtained are entirely consistent with results from mutagenesis studies identifying particular residues as being critical for the interaction. As with the structural biological analysis of IgG, the analysis of the Fc–FcR interaction again shows a large element of asymmetry in the behavior of the proteins.

In the crystal structure, the FcγRIII molecule uses principally domain 2 to make contact with the Fc molecule, and only two residues from the linker between the first and second receptor domains also participate in making contacts with the Fc piece (Sondermann et al. 2000). The key regions of the Fc piece involved in the receptor interaction are the Cγ2 domain and the lower hinge region; as expected Leu-234 and Leu-235 residues of the Fc piece make contact with receptor elements. The contact between the receptor and the Fc region Cγ2 domains is asymmetrical, with one Cγ2 domain having more surface area buried in the interaction (23.34 nm^2) than the other (18.70 nm^2).

The contact region involves five discrete stretches of three to four amino acids of the receptor domain binding to three regions of the Cγ2 domain: the Leu234–Ser239 region of both lower hinges and an *N*-acetylglucosamine group of the Fc region carbohydrate (Sondermann et al. 2000). The physical interactions are mainly van der Waals' and hydrogen bonds, many of which are contributed by residues 234–239 in the lower hinge. These latter lower hinge regions are one of two main regions of contact in the crystal, the other being Pro329 of one Cγ2 domain which is found in a 'proline sandwich' secured tightly by two tryptophan residues (Trp89 and -110) of the receptor.

The interaction of the Fc piece with the receptor causes large changes in the structures of each participant (Sondermann et al. 2000). In the unliganded receptor, the elbow angle between the two domains is about 70°, but this opens up on interaction with the Fc region to some 80°. The Fc piece also 'opens up' on binding to the receptor, with the tips of the two Cγ2 domains being pushed 0.7 nm further apart than is observed in the free Fc structure. The interaction of the *N*-linked oligosaccharides in the Fc piece is also altered with the terminal mannose residues moving from 0.28 nm to 0.53 nm apart. One consequence of the conformational change and asymmetrical nature of the interaction is that binding of a second FcR molecule to the IgG Fc region is precluded, thereby enforcing a 1:1 stoichiometry of interaction of receptor and IgG.

CELLULAR BASIS OF ANTIBODY PRODUCTION

Theories of antibody production

The primary structural analysis of Ig molecules indicates that the humoral immune system is capable of recognizing a vast array of antigens in a specific manner. Two schools of thought emerged to account for this diversity: instruction of the immune system by each antigen or selection of pre-existing antibody by antigen. Evidence to support the selective theory was provided by studies of denatured and reduced Fab fragments of purified anti-RNAse antibody (Haber 1964). Reactivity to RNAse was always recovered after renaturation in the absence of RNAse, indicating that antigen (RNAse) did not 'instruct' the antibody to recognize it. Thus, the information for antibody specificity must be contained in the primary structure of the immunoglobulin.

The clonal selection theory (Burnet 1959) was developed to provide a framework to explain the synthesis of antibody molecules by B lymphocytes. All B lympho-

cytes, whether responding to antigen for the first time or daughter memory cells undergoing activation in response to re-challenge, obey the rules of this theory. The principal tenets of this theory are:

- The capacity to respond to a given antigen exists before antigen exposure.
- Each B lymphocyte possesses a single receptor specificity for antigen.
- The binding specificity of the receptor is identical to that of the antibody that the cell will secrete in response to antigen binding.
- Specific antigen is the sole signal for clonal expansion.
- The antibody produced by a cell is subject to allelic exclusion (i.e. only one set of antibody-determining genes is activated).

B lymphocytes are the cellular site of synthesis of antibody molecules. B lymphocytes, like all blood cells in mature mammals, initiate their development in the bone marrow and are derived originally from pluripotent hemopoietic stem cells. Some early B-cell progenitors are found in fetal liver and the yolk sac and, in avian species, B cells develop in the cloacal organ, the bursa of Fabricius. Moreover, in murine models, there are good data demonstrating the development of a self-repopulating B-cell subset (variously called Ly-1$^+$, CD5$^+$, or B-1 B cells) in the peritoneal cavity. In all cases, however, the B-cell development program is a multistage process, and regulation of differentiation is achieved by stepwise expression of key genes, accurate rearrangement of Ig genes, cell–cell adhesion and soluble signals from bone marrow stromal elements or other cell types in the periphery, and contact with antigen (Figure 6).

Antigen-independent B-cell development

The development of mature B cells from pluripotent hemopoietic stem cells is a complex process during which regulated rearrangement of the germline Ig heavy (*Igh*) and Ig light (*Igl*) genes takes place. B-cell differentiation can be divided into two anatomically and functionally distinct stages. The first phase of development is antigen independent, occurs in the bone marrow, and is concerned with generation of a specific receptor for antigen (i.e. successful somatic recombination of Ig heavy and light chain genes). The second phase of B-

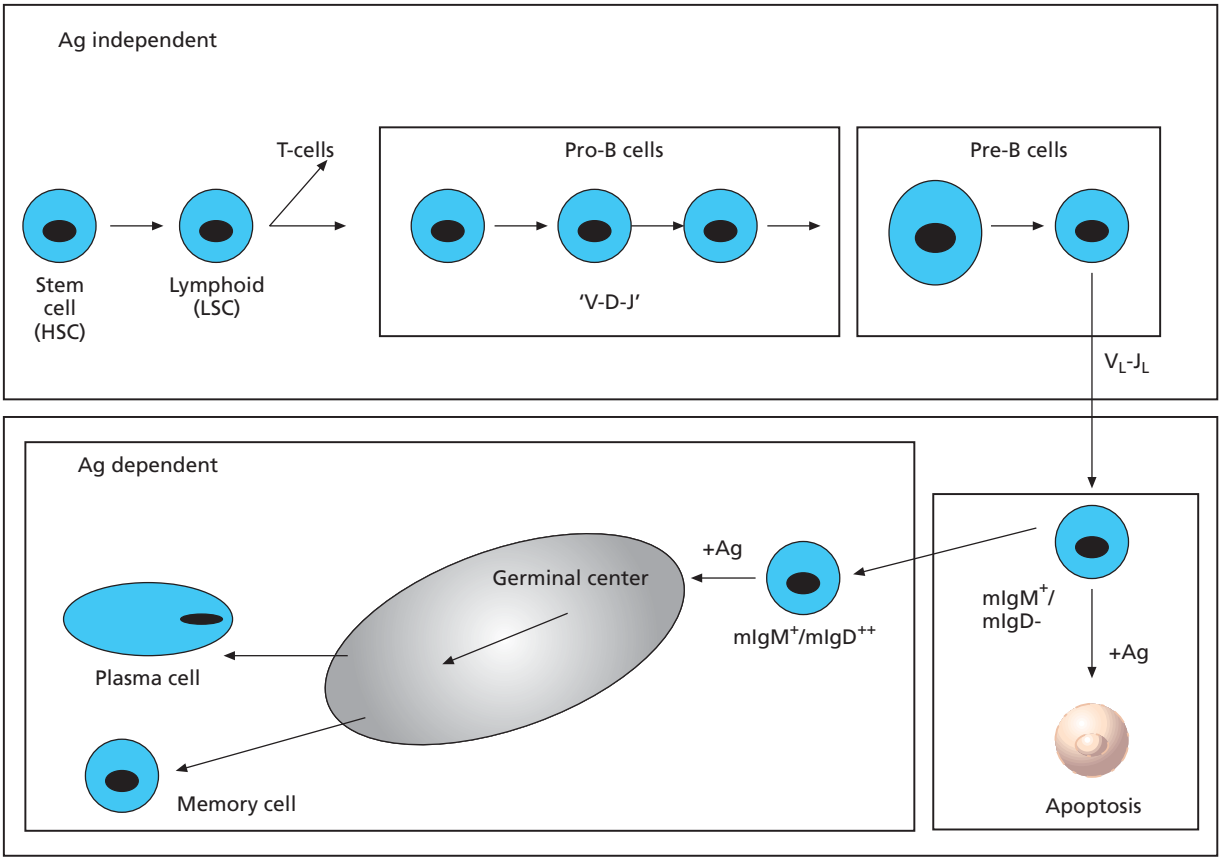

Figure 6 *A route map of B-cell differentiation: the main stages of B-cell development are shown. The upper panel illustrates the antigen-independent phase of development, occurring largely in the bone marrow, whereas the lower panel describes antigen-dependent events in the periphery.*

lymphocyte development is antigen dependent and occurs in the peripheral lymphoid system. In this second phase of development, the fate of B cells expressing clonally distributed receptors for antigen (i.e. membrane Ig or 'BcR') is inextricably linked to contact with specific antigen. This contact can result in clonal deletion or anergy, clonal expansion or prevention of apoptosis, and recruitment into the memory B-cell pool, with the outcome being dependent on the stage of differentiation of the B cell upon contact with antigen. A number of checkpoints and selection steps ensure that only cells expressing functional Ig heavy and light chains, which can associate into cell-surface IgM that is not autoreactive, are allowed to progress to the mature B-cell stage.

The first step in progression along the pathway of antigen-independent B-cell development in the bone marrow is differentiation of pluripotent stem cells into $CD34^+$ bipotential lymphoid stem cells (LSC). These LSCs can, depending on the transcription factors activated in this cell, become either a T-cell precursor ($CD2^+$ or $CD7^+$) or a B-cell precursor ($CD19^+$). The earliest stage at which cells committed to the B lineage can be detected is known as the pro-B-cell stage. These cells express some B-cell-specific markers (e.g. CD19), and undergo the process of *Igh* rearrangement (Hardy et al. 1991). Once the *Igh* locus has been successfully rearranged, the resulting μ chain is expressed on the surface as part of the pre-B-cell receptor (pre-BcR, described below), and the cells undergo the burst of rapid proliferation that is characteristic of the early (large) pre-B-cell stage (Kurasuyama et al. 1994). This stage of proliferation means that each productively rearranged IgH chain is duplicated in many daughter cells and has the opportunity to associate with many different IgL chains; the *Igl* locus is rearranged during the next stage of development, that of the small (late) pre-B cell. The cytokine interleukin IL-7, produced by bone marrow stromal cells, is important during these early stages of B-cell development in the mouse, particularly in its ability to stimulate proliferation of the cells (Corcoran et al. 1996). Mice deficient in IL-7, the IL-7 receptor α chain, or the cytokine receptor common γ chain (γc) have severely impaired B-cell development (Peschon et al. 1994; Cao et al. 1995; von Freeden-Jeffry et al. 1995). However, IL-7 appears to be much less important during human B-cell development, and has only a weak proliferative effect on normal human B-cell precursors in vitro (Wolf et al. 1991). One form of the disease severe combined immunodeficiency (SCID) is caused by a lack of the γc chain required for IL-7 signaling, but although they have few T cells or NK cells, patients with this disease have normal peripheral B-cell numbers (Noguchi et al. 1993).

Productive rearrangement of *Igl* leads to the cell surface expression of heavy (μ) and light (κ or λ) chain on the cell surface as intact IgM, at which point the cells enter the immature B-cell stage. This is the stage at which negative selection of autoreactive B cells occurs, resulting in B-cell tolerance. Thus, only non-self-reactive B cells are able to exit the bone marrow and enter the periphery, where they complete their development into mature B cells, which express cell-surface IgM and IgD and can be activated on binding of antigen.

Selection during antigen-independent B-cell development

Selection of B cells occurs throughout their development. One of the most important and best-characterized selection events is for pre-B cells, which are capable of expressing the pre-BcR. Once IgH rearrangement is complete, μ chain is expressed on the cell surface as one component of the pre-BcR; the other components are the surrogate light chains λ_5 and $V_{pre\text{-}B}$, products of B-cell-specific, non-rearranging genes, and the signaling components Igα and Igβ. Only μ chains resulting from in-frame *Igh* recombination and capable of binding κ or λ light chain after *Igl* rearrangement will be able to associate with the rest of the pre-BcR and allow signaling through this receptor. Productive rearrangement and the resulting pre-BcR signaling lead to proliferation of the cells (Kurasuyama et al. 1994); those cells with non-productive rearrangements cannot form the pre-BcR and/or signal through that complex, and so will not progress further through the B-cell developmental pathway. Proliferation induced by pre-BcR signaling appears to be self-limiting, as production of the λ_5 surrogate light chain component ceases once the pre-BcR is expressed on the cell surface. Thus, the expression level of the pre-BcR and the proliferative signals transduced by it reduce as proliferation progresses, until the cells no longer receive the proliferative signal and so exit the cell cycle. No ligand has yet been identified for the pre-BcR, and it has been speculated that no such ligand exists. Thus, it is possible that it is simply the expression of the pre-BcR on the cell surface that causes the complex to signal, rather than binding of an extracellular ligand to the complex.

The importance of signaling through the pre-BcR is demonstrated by the effect of loss of activity of the Bruton's tyrosine kinase (Btk), a defect that results in X-linked agammaglobulinemia (XLA) (Vetrie et al. 1993). Btk is an important component of the pre-BcR (and, indeed, of the mature BcR) signaling pathway and its loss results in a defect in the ability of pro-B cells to progress to the pre-B-cell stage and proliferate (Nomura et al. 2000). Thus, XLA patients have reduced numbers of pre-B cells (and therefore also of mature B cells), with the severity of the reduction in numbers varying depending on the precise Btk mutation inherited by the patient (Hashimoto et al. 1999). Interestingly, loss of Btk function in mice, by either natural mutation or targeted gene disruption, results in a much less severe phenotype than seen in human XLA (Scher 1982;

Kerner et al. 1995). These data suggest a lesser reliance on Btk in early murine B-cell development than in human B-cell development.

Expression of the intact μ chain and the pre-BcR also leads to allelic exclusion at the *Igh* locus; recombinase activating gene products (RAG) 1 and 2 are degraded, and presumably alterations in transcription factor expression at the pro-B- to pre-B-cell transition reduce the accessibility of the *Igh* locus, preventing further recombination (Grawunder et al. 1995). Thus, only a single productively rearranged Igh locus is present in each pre-B cell. The ability of a productively rearranged *Igh* locus to induce allelic exclusion has been convincingly demonstrated using mice transgenic for a particular V_HDJ_H gene combination: the only μ chain expressed is that of the transgene, indicating that its presence and ability to associate in the pre-BcR prevent rearrangement of either of the endogenous IgH alleles (Nussenzweig et al. 1987).

The next stage at which B cell selection takes place is after rearrangement of the *Igl* locus. In a manner similar to that of selection of pre-B cells, which can successfully associate intact μ chain in the pre-BcR, only those cells in which the product of the newly recombined κ or λ light chain gene can associate with existing μ chain to allow expression of IgM on the cell surface in association with Igα and Igβ and form the mature BcR can progress further. The signal resulting in this positive selection is not known, but successfully selected cells go on to become surface-expressing immature B cells, and undergo the next level of selection.

So far, cells have only been selected for the ability to express intact and functional μ and κ/λ chains; there has been no negative selection to remove those cells that express autoreactive receptors. This occurs at the immature cell stage. Interestingly, it seems that not all autoreactive cells are immediately deleted; instead, cells expressing self-reactive surface IgM can enter a process known as 'receptor editing', during which secondary rearrangements at the *Igh* and/or *Igl* loci change the antigen specificity of the BcR expressed (Tiegs et al. 1993). If receptor editing does not succeed, self-reactive immature B cells undergo anergy or apoptosis on encounter with antigen. This contrasts with the ability of mature B cells to become activated on encounter with antigen: mature cells become activated, whereas immature cells die by apoptosis. The differences in signaling mechanisms underlying these radically different responses to antigen at the immature and mature B-cell stages are considered in detail in The B cell antigen receptor.

Transcriptional control of B-cell development

So far, the mechanisms of B-cell development, but not of the control of the developmental pathway, have been discussed. This takes place through the expression of various transcription factors, which regulate the activation of lineage-appropriate genes, the repression of genes associated with development of other hemopoietic lineages, and through control of the accessibility of the *Igh* and *Igl* loci to the recombination machinery. Several of the most important and best-studied transcription factors are considered here.

PU.1

PU.1 is a member of the Ets family of transcription factors, and is expressed in monocytic, granulocytic, and lymphoid lineages (Klemsz et al. 1990). Ets sites, which can be bound by PU.1 in association with various other proteins, are found in a number of genes important in B-cell development, including *Igh* and *Igl* genes, RAG1, components of the pre-BcR, Btk, and terminal deoxynucleotidyl transferase (TdT) (Kozmik et al. 1992; Omori and Wall 1993; Ha et al. 1994; Fitzsimmons and Hagman 1996; Muller et al. 1996). PU.1-deficient mice lack both B- and T-cell precursors, and die before birth (Scott et al. 1997), but experiments in which PU.$1^{-/-}$ embryonic stem cells or fetal liver cells were transferred to irradiated normal animals suggests that this transcription factor is especially important in the development of a multipotential lymphomyeloid precursor cell (Scott et al. 1997). Although PU.1 is expressed in cells from various hemopoietic lineages in normal animals, it appears to play a role in lineage commitment. Retroviral transfer of PU.1 to PU.$1^{-/-}$ lymphomyeloid progenitor cells from fetal liver rescued development of both B cells and macrophages, but the macrophages expressed significantly higher levels of PU.1 than the B cells (DeKoter and Singh 2000); these experiments also demonstrated that overexpression of PU.1 inhibits B-cell development. Thus, PU.1 operates very early in hemopoietic development, at the level of multipotent precursors and lineage commitment.

IKAROS AND AIOLÖS

Ikaros is mainly expressed in hemopoietic cells, particularly in B-cell precursors, suggesting a role for Ikaros in B-cell development. Ikaros-deficient mice lack fetal B and T cells, but only peripheral B cells are missing from the adult mice (Wang et al. 1996). The block in B-cell development caused by loss of Ikaros is before the pro-B-cell stage (Wang et al. 1996), and Ikaros-binding sites have been identified in the promoters of RAG1, Igα, V_{preB}, λ_5, and TdT genes (Georgopoulos et al. 1997). In the TdT promoter, the Ikaros-binding site overlaps an Ets-binding site, suggesting that Ikaros and Ets transcription factors may compete for binding here (Ernst et al. 1996).

Aiolös is a member of the Ikaros family of proteins but is expressed later in development than Ikaros itself (Morgan et al. 1997). Aiolös is first detected in

committed B- and T-cell precursors, and its expression levels increase as the cells mature (Morgan et al. 1997). Aiolös-deficient mice have increased numbers of pro- and pre-B cells, suggesting a defect in differentiation of the cells to the later stages of antigen-independent development (Wang et al. 1998). Such mice also show defects in mature B-cell functions, including isotype switching in the absence of immunization, proliferation in response to very low levels of BcR signaling, and the formation of B-cell lymphomas (Wang et al. 1998). In contrast to Aiolös$^{-/-}$, Ikaros$^{+/+}$ mice, animals that are Aiolös$^{-/-}$ Ikaros$^{+/-}$ have decreased numbers of both pre-B and mature B cells (Cortes et al. 1999), suggesting that these two transcriptional regulatory proteins act together. In fact, the two proteins are expressed in a complex in both developing and mature B-cell populations. Mature B cells in Aiolös$^{-/-}$ Ikaros$^{+/-}$ mice are also more readily activated than those derived from Aiolös$^{-/-}$ Ikaros$^{+/+}$ mice (Cortes et al. 1999), indicating that the two proteins may also act in concert to regulate signaling thresholds for B-cell activation through the BcR.

E2A

Alternate splicing leads to the production of two proteins from the *E2A* gene, known as E12 and E47 (Murre 1994). These basic helix–loop–helix transcription factors are members of the E protein family (also known as class I HLH proteins), the members of which homo- or heterodimerize (to other E proteins or to members of the class II HLH family) to allow binding to the sequence CANNTG, known as an E-box site. This sequence is found in the promoter of a number of B-lineage genes, including Igα and λ_5 (Sigvardsson et al. 1997). E12 and E47 are ubiquitously expressed, but are especially important in B-cell development, where B-cell-specific phosphorylation allows the E47 protein to form a DNA-binding homodimer (Sloane et al. 1996). In other tissues, E proteins such as E12 and E47 usually heterodimerize with class II HLH proteins; thus such homodimerization is tissue specific. E12 and E47 act early in B-cell development, and mice deficient in E2A have B cells that are blocked at the very early pro-B cell stage, before DJ_H rearrangement, and have virtually no mature B cells (Bain et al. 1994). These cells also do not express proteins associated with B-cell commitment and development, such as Igα and RAG1, underlining the important role played in early B-cell development by the E2A proteins (Bain et al. 1994, 1997; Zhuang et al. 1994).

The early and profound block in B-cell development seen in E2A$^{-/-}$ mice means that these mice cannot be used to identify genetic targets of the E12 and E47 transcription factors, or their potential roles in later B-cell development. Thus, alternate strategies, such as transfection of non-B-lineage cell lines with E12 or E47, must be employed. Such studies have shown that, in various cell lines, expression of E47 results in production of germline Ig transcripts, the RAGs and TdT, suggesting an involvement in regulation of Ig rearrangement as well as lineage commitment (Schlissel et al. 1991; Choi et al. 1996; Romanow et al. 2000). Indeed, when E47 and the RAG genes are expressed in a human embryonic kidney carcinoma cell line, both *Igh* DJ and Igκ VJ rearrangements are seen (Romanow et al. 2000). Rather than the transcription factors acting directly in V(D)J recombination, however, it appears that binding of E2A proteins to Ig enhancers increases the accessibility of these loci to the recombination machinery. Transfection of E12 into a macrophage cell line that has rearranged *IgH* and Igκ genes, but which does not express cell surface IgM, results in the induction of a number of B-cell-specific genes, including RAG-1, EBF, λ_5, and *Pax5* (Kee and Murre 1998). It is also notable that there is a gene dosage effect for E2A proteins in B-cell development. Thus E2A$^{+/-}$ mice have 50 percent of the numbers of B cells found in E2A$^{+/+}$ animals (Zhuang et al. 1994). This effect is explained by the Id protein family discussed below.

Another means of investigating the roles of E2A proteins in B-cell development is to transfect members of an E2A-inhibiting family known as Id proteins into E2A-expressing cells. These Id proteins are related to the E proteins, containing the domain that allows them to heterodimerize with E proteins but not the DNA-binding domain (Sun et al. 1991). Thus, expression of Id proteins causes E proteins to be 'trapped' in non-DNA-binding E–Id heterodimers, effectively inhibiting the function of the E proteins. Mice expressing an *Id1* transgene exhibit the same block in B-cell development as E2A-deficient mice, and the severity of the block is dependent on the level of expression of the transgene, i.e. on the amount of E2A proteins that can be sequestered by *Id1* (Sun et al. 1991).

EBF

As mentioned above, transfection of cell lines with E2A proteins has shown that these transcription factors can induce production of early B cell factor (EBF) (Kee and Murre 1998). This is supported by the observation that, although EBF-deficient mice, similar to E2A$^{-/-}$ mice, exhibit an early block in B-cell development (Lin and Grosschedl 1995), the few B-cell precursors that are found express E12 and E47, indicating that E2A expression is not dependent on EBF expression (Lin and Grosschedl 1995). A number of B-cell-specific genes have binding sites for EBF in their promoters, including Igα, Igβ, and λ_5 (Kee and Murre 1998), indicating that expression of these proteins may be directly regulated by EBF. EBF and the E2A transcription factors appear to act together to regulate certain B-cell-specific genes, such as the components of the surrogate light chain, and binding sites for both EBF and E47 are present in the λ_5 promoter (Sigvardsson et al. 1997).

PAX5/BSAP

Expression of the *Pax5* gene, encoding the B-cell stimulatory/activatory protein (BSAP) protein, is regulated by the E2A and EBF transcription factors; EBF binds to a site in the *Pax5* promoter, and activates transcription. The BSAP protein is expressed in all committed B cells from the pro-B stage until activation of mature B cells; plasma cells do not express this transcription factor (Busslinger and Urbanek 1995). Interestingly, BSAP appears to function as both a transcriptional activator and a repressor: it activates genes for B-cell-specific proteins such as CD19 and the surrogate light chains, but represses genes associated with other hemopoietic lineages (Kozmik et al. 1992; Nutt et al. 1998, 1999; Wallin et al. 1998). This dual function is dependent on *Pax5* protein levels in the cell; transcriptional activatory sites have a higher affinity for *Pax5* than repressive sites (Wallin et al. 1998), and so the activation functions of this transcription factor can be carried out when the protein is present at lower levels than is necessary for repression. B-cell development in mice deficient in *Pax5* is blocked at the pro-B-cell stage (Nutt et al. 1997), i.e. slightly later in the differentiation pathway than is seen in the E2A$^{-/-}$ and EBF$^{-/-}$ mice; this is consistent with the regulation of *Pax5* by EBF. The role of *Pax5*/BSAP in B-cell commitment has recently been demonstrated in vitro, using pro-B cells from *Pax5*$^{-/-}$ mice. Under suitable culture conditions, these cells, which appear to be committed to the B-cell lineage, can differentiate into a variety of other hemopoietic lineages, including macrophages, granulocytes, and T cells (Nutt et al. 1999). Thus, expression of *Pax5* appears to be vital to allow very early B cells to commit irreversibly to the B lineage.

Thus, B-cell commitment and development are controlled by the sequential expression of a number of transcription factors that control the developmental pathway by activating those genes required for B-cell differentiation and repressing lineage-inappropriate genes.

Antigen-dependent B-cell development

Recirculating mature B cells in the periphery die after several weeks or months unless they encounter an antigen containing epitope(s) recognized by the cell's BcR. Numbers of mature B cells are maintained by the continual replacement of 'old' B cells by newly developed cells that have emigrated from the bone marrow.

B cells can be activated in either the presence or absence of help from T cells, depending on the type of antigen encountered. T-independent (TI) antigens can themselves provide the co-stimulatory signals required for B-cell activation, either through binding non-BcR cell-surface receptors that cause B-cell activation, or through extensive crosslinking of the BcR by highly repetitive antigens. TI antigens usually lead to low-affinity IgM responses. Mature B cells that are activated by T-dependent antigen in the presence of co-stimulatory signals undergo further differentiation, which allows the cells to:

- introduce mutations into their IgH and IgL chain genes to increase affinity for the antigen (somatic hypermutation)
- change the isotype of the antibody produced (class or isotype switching)
- become either antibody-secreting plasma cells or memory B cells.

This affinity maturation of B-cell responses occurs in specialized structures within lymph nodes known as germinal centers, and allows the humoral response to become faster and more efficient on future contact with the same antigen.

B-CELL ACTIVATION

Most immune responses require both contact between, and activation of, B and T cells recognizing the same antigen (although not necessarily the same epitope on that antigen). Binding of specific antigen by B cells leads to signaling through the BcR, which activates the B cell. In addition, the antigen–BcR complex is internalized by the B cell; the antigen is processed and then presented on the cell surface in association with MHC class II molecules. In the T-cell area of the lymph node, antigen-presenting B cells interact with antigen-specific CD4^{+} helper T cells, which have been primed by encounter with the antigen presented on MHC class II by interdigitating dendritic cells in the lymph node. Only B cells that interact with T cells that have been activated by the same antigen will go on to differentiate further.

The interaction of B cells with antigen-specific T cells involves a number of receptor–ligand pairs on the two cell types in addition to the MHC class II–T cell receptor interaction. Various adhesion molecule pairs, such as leukocyte function-associated antigen-1 (LFA-1) and intercellular adhesion molecule 1 (ICAM-1), each of which is expressed on both B and T cells, contribute to stabilizing the interaction. These adhesion molecules can also transduce signals into the cells that contribute to B-cell activation, although the signaling pathway(s) used is not clear.

Perhaps the most important co-stimulatory interaction that takes place during B-cell activation is that of CD40 (on B cells) and its ligand (CD40L or CD154) on activated T cells and follicular dendritic cells (FDC) (Gordon and Pound 2000). Engagement of CD40 by its ligand promotes a variety of functions involved in enhancement of B-cell responses, including proliferation, antibody synthesis, cytokine production, and isotype switching. Once activated, B cells are predisposed to apoptose in the absence of survival signals at various checkpoints during antigen-dependent differentiation;

signaling though the CD40–CD40L interaction is an important survival signal for the cells and inhibits apoptosis of germinal center B cells in vitro. The importance of CD40-mediated signaling is underlined by the effects of a mutation in the gene for CD40L, which results in the immunodeficiency disease X-linked hyper-IgM syndrome (Kroczek et al. 1994). Patients with this disease have impaired antibody responses, mainly caused by an inability of B cells to undergo class switching and affinity maturation, resulting in overproduction of low-affinity IgM antibodies (see 'Mechanisms of somatic recombination' below). Additional signals are received by B cells through interactions between B-cell surface CD80 (B7–1) or CD86 (B7–2) and T-cell CD28 (Jeannin et al. 1997). These interactions are also important in the co-stimulation of T cells by signaling through CD28. CD80 and CD86 are expressed on centrocytes, but not on centroblasts.

Once B cells are activated by encounter with antigen-specific, activated, helper T cells, they can differentiate immediately into antibody-secreting plasma cells. These plasma cells will usually produce only low-affinity antibody, of the IgM isotype, but allow specific antibody to be secreted while other B cells undergo additional differentiation to produce higher-affinity antibodies of different isotypes. Those activated B cells that do not develop into plasma cells at this stage enter the primary follicle in the lymphoid tissue, adjacent to the T-cell area where they have been activated, and initiate the formation of a germinal center (Maclennan 1994). The germinal center consists of a dark zone containing centroblasts (B cells rapidly proliferating and undergoing somatic hypermutation) and a light zone containing centrocytes (B cells undergoing selection for high-affinity BcRs after somatic hypermutation has taken place).

SOMATIC HYPERMUTATION, CLASS SWITCHING, AND SELECTION

The process of somatic hypermutation introduces mutations into the IgH and IgL V(D)J regions; these are usually point mutations, although deletions and duplications are also occasionally found (Goossens et al. 1998). The mechanism by which mutation occurs is not well understood, and although upregulation of the RAG genes is found in germinal center B cells (Han et al. 1996), the type of gene rearrangement seen in earlier stages of B-cell development does not seem to occur. There is some evidence to suggest that mutations are introduced by a form of error-prone, DNA-repair system. Whatever the method used, the process of hypermutation introduces mutations into the V(D)J region at a rate of approximately 1 change per 10^3 base-pairs/cell per generation (McKean et al. 1984).

Introduction of mutations does not necessarily lead to increased affinity for the antigen; many mutated BcRs will have reduced affinity or will even become potentially autoreactive. Thus, some form of selection must operate to allow those B cells with increased affinity to survive, and those with reduced affinity or altered antigen specificity to be lost. As mentioned above, germinal center B cells are predisposed to apoptose in the absence of survival signals, and these survival signals are dependent on the ability of the BcR to interact with antigen and of the cell to present antigen to specific T-helper (Th) cells and receive survival signals from them (Liu et al. 1991b). Therefore, after somatic hypermutation has taken place, the centroblasts move from the dark zone of the germinal center to the light zone, where they become centrocytes and can interact with mature FDCs present in this area. These FDCs express a number of cell-surface receptors, including complement receptors and Fc receptors, which allow them to bind large quantities of immune complexes and retain them for long periods of time on the cell surface. Centrocytes compete for access to these immune complexes, resulting in rescue signals (e.g. through the CD40–CD40L interaction (Gordon and Pound 2000)) from the FDCs for only those centrocytes expressing the highest affinity BcRs. Those cells that are selected (i.e. those with high-affinity BcRs) are able to acquire and process the antigen from the FDCs and present it on class II MHC to T cells, receiving a further survival signal from the antigen-specific Th cells at this stage. These two stages of selection ensure that only cells with high-affinity BcRs, which recognize antigen that is also recognized by T cells, are allowed to survive passage through the germinal center; other cells die by apoptosis. This prevents the survival of centrocytes that recognize self-antigen after somatic hypermutation, because, even if the self-antigen is present on FDCs, no T cells specific for that antigen will be present.

As discussed earlier, antibody molecules can carry out different effector functions by utilizing different C regions in the *IgH* gene. Switching is dependent on engagement of B-cell CD40 by its ligand (Kawabe et al. 1994), and the production of different cytokines by Th cells which induce switching to specific Ig isotypes, e.g. activation of B cells in the presence of IL-4 leads to production of IgE (Th2-type response), whereas IFN-γ causes switching to IgG3 and $IgG2_2$ (Th1-type response). The molecular mechanisms underlying immunoglobulin isotype switching are discussed under 'Class switch recombination' below.

B cells that have undergone somatic hypermutation and class switching can either form high-affinity plasma cells in the lymph nodes or bone marrow, which secrete large amounts of specific, high-affinity antibody of the appropriate isotype for 2–3 weeks before dying, or become long-lived memory B cells. These memory B cells retain the antigen specificity and antibody isotype determined by their differentiation in the germinal center, and remain in the lymph node until they again encounter antigen. At this time, they become activated

more quickly than naïve B cells, allowing a faster response to antigen; they also have greater capacity for presenting antigen to T cells, through higher expression of MHC class II and co-stimulatory molecules such as CD80 and CD86.

IMMUNOGLOBULIN GENES AND ANTIBODY DIVERSITY

Antibody diversity

The adaptive immune system must be able to generate a very large number of different antibodies (or BcRs and hence B lymphocytes) in order to recognize all possible antigens that may be encountered by the host. The same is true of T-cell receptors (TcR). However, the size of the genome is finite, and so genetic mechanisms must exist to enable a large number of gene products (Ig chains) to be assembled from a limited number of genes. How is this achieved?

The pioneering experiments of Tonegawa and his colleagues demonstrated that the genetic elements encoding V and C regions of the polypeptide are located some distance from each other in the DNA of non-B cells, but are fused together in antibody-synthesizing B cells (Hozumi and Tonegawa 1976). Indeed, in the case of the genetic material encoding V-region sequences, multiple separate elements were shown to be involved. Thus, for κ chains, there are multiple V genes (250–300) and four functional J 'mini-genes'. V and J genes are separated by a great distance in germline DNA but, in a B cell, one V element is found joined to a single J element, giving a continuous unit of VJ information, i.e. V and J elements undergo somatic recombination. The joining of any V gene to any J gene (or DJ for heavy chains) results in deletion of all intervening DNA. A simple arithmetic calculation reveals that between 1000 and 1200 different VJ units can be formed by somatic recombination at the κ locus. A similar rearrangement of V and J information is observed at the λ locus (Figure 7).

At the heavy chain locus, there is an additional mini-gene family located between the V and J genes, called the D (diversity) genes. Two somatic recombination events are therefore required at the heavy chain locus to give a complete and active V gene. These occur in the order of one D and one J element being recombined to give a DJ unit, followed by fusion of this DJ gene to a single V gene to give a continuous *VDJ* gene (Coleclough et al. 1981). Clearly, therefore, the capacity to rearrange members of mini-gene families randomly greatly expands the final number of total genes and proteins available as antibodies or BcRs. Finally, somatic recombination is independent of antigen, and successful recombination on one of the two chromosomes bearing a given Ig gene prevents rearrangement on the other chromosome (allelic exclusion), thus conforming to the rules of the clonal selection theory.

V(D)J recombination: signals and rules

The recombination process is controlled by highly conserved nucleotide sequences flanking the genes to be rearranged. For V genes examination of sequences lying 3′ to the end of the coding elements revealed the presence of a conserved heptameric sequence linked by a spacer to a similarly highly conserved nonameric sequence. These are called recombination signal sequences (RSS). The size of the spacer between the heptanucleotide and nonanucleotide RSSs is always either 12 ± 1 or 23 ± 1 nucleotides, even though the sequence itself is not highly conserved. Indeed, recombination can occur only between mini-genes flanked by RSSs with different-sized spacers, i.e. one partner must have a 12-nucleotide spacer and the other a 23-nucleotide spacer. This is the so-called 12/23 rule. The recombination process is mediated by the RAG products, and is not exact, and shifts in the frame of recombination can increase diversity. In the case of fusion to the D genes, the enzyme terminal deoxyribonucleotidyl transferase can add nucleotides (usually G) to 3′-hydroxyl groups a nontemplate-directed manner; these are referred to as Nucleotide (N) regions. There are also small regions of palindromic repeats found at V(D)J joints and these are referred to as P sequences.

Mechanisms of somatic recombination

The V(D)J recombination process can be divided into four main steps: alteration of chromatin structure to allow access of the recombination machinery; recognition and binding of RSS; cleavage of DNA; and DNA repair and closure of joints. The joints formed are a 'coding joint', which brings together V and J sequences, and a signal joint which forms a closed circle containing the intervening DNA lost as a function of the recombination reaction. Signal joints are always precise, whereas coding joints are variable, a feature that is important in generation of antibody (and TcR) diversity. The proteins participating in V(D)J recombination are drawn from both lymphocyte-specific enzymes required for RSS recognition and cleavage and from ubiquitously expressed proteins involved in DNA repair and chromatin dynamics.

Highly condensed chromatin is likely to impede access of RAG complexes to Ig genes and associated RSS motifs (Roth and Roth 2000). Indeed, in in vitro assays mononucleosomes are able to inhibit the recombination reaction (Kwon et al. 1998; McBlane and Boyes 2000), largely by inhibiting the binding of the RAG complex to the RSS (McBlane and Boyes 2000; Kwon et al. 2000). Studies of histone acetylation have suggested that the

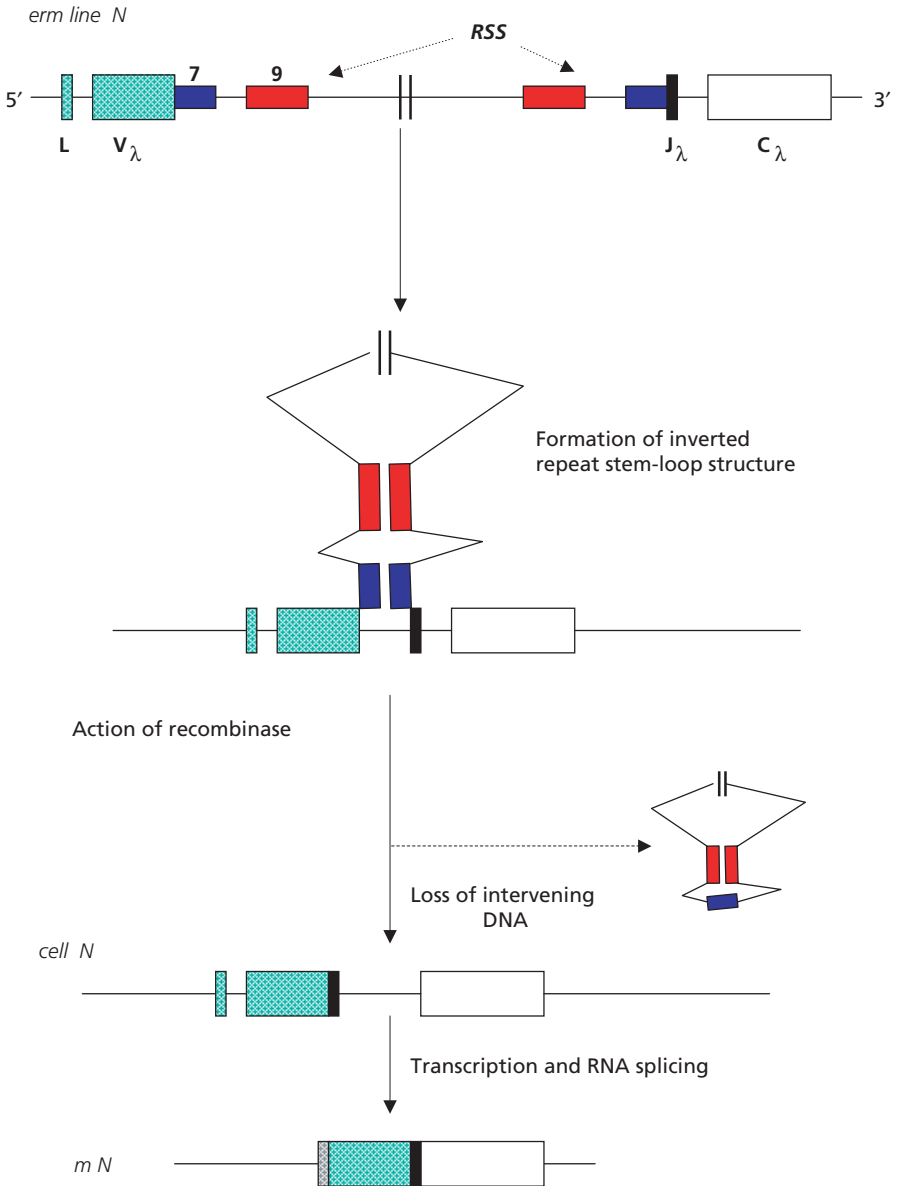

Figure 7 *Immunoglobulin λ chain gene rearrangement: the organization of the Igλ locus in germline and B-cell DNA is illustrated. Vλ and its associated leader peptide exon (L) are shown as stippled boxes, Jλ as a solid black box and Cλ as a solid white box. The heptameric and nonameric RSS are shown in blue and red, respectively. Intronic sequences are depicted by the thin line, and exons by boxes.*

level of acetylated histone H3 correlates with the degree of V(D)J recombination observed in vivo, indicating that local chromatin remodeling caused by acetylation favors recombination (McMurry and Krangel 2000). In many models, histone acetylation is greatly increased in those parts of the chromatin where transcription is viable.

Using the λ light gene as the model (see Figure 7), a large single-stranded stem-loop structure is formed by pairing of complementary heptanucleotide and nonanucleotide RSSs separated by 12 and 23 spacer sequences. This structure is bound by a tetrameric RAG1–RAG2 protein complex consisting of two molecules of each RAG (Bailin et al. 1999; Sadofsky 2001). RAG1 has demonstrable affinity for the nonanucleotide RSS (Difilippantonio et al. 1996; Mo et al. 1999), but it remains to be demonstrated unequivocally that RAG2 binds DNA (although this seems likely (Mo et al. 1999)). The enzyme complex introduces a single nick in each DNA strand, precisely cleaving the phosphodiester bond between the final base of the coding sequence and the first base of the heptameric RSS (McBlane et al. 1995). The free hydroxyl group at the 3′ of the coding strand now attacks the phosphodiester bond at the same position on the opposite strand, forming a closed hairpin loop at the coding joint. Plainly, hairpins are formed at both the V and the J coding joints, and the remaining

products are blunt and 5′-phosphate-bearing ends of the signal joint. The signal joints are precisely closed in a process requiring the RAG proteins, but, more importantly, the normal enzymes of DNA repair (Ku proteins, XRCC4, and DNA ligase IV) (Jeggo 1998).

In order for V-J joining to proceed, the hairpin loops must now be opened. As with signal joints, the RAG and Ku proteins appear to be mandatory for hairpin opening, but the process also requires DNA-dependent protein kinase catalytic subunit (DNA-PKcs) and the Artemis double-stranded DNA repair protein (Schlissel 2002). Artemis itself possesses a Mg^{2+}-dependent exonuclease activity but normally has no endonuclease activity. However, Artemis forms a complex, both in vivo and in vitro, with DNA-PKcs and is a substrate for the kinase activity of DNA-PKcs (Ma et al. 2002). In this complex, phosphorylated Artemis now expresses an endonuclease activity and is capable of opening hairpin loops using water as nucleophile for cleavage of target phosphodiester bonds. Support for the hypothesis that the Artemis–DNA-PKcs complex opens hairpins at V and J coding joints is provided by the rare human condition of radiation-sensitive SCID (RS-SCID). Fibroblasts from RS-SCID patients have a specific defect in V(D)J recombination in that no coding joints are formed, implying an inability to open hairpins; the sole genetic defect in RS-SCID is the Artemis enzyme activity (Moshous et al. 2001).

The action of the Artemis–DNA-PKcs complex opens the hairpin loops, leaving overhanging ends, generally of two to seven nucleotides (Livak and Schatz 1997; Schlissel 1998), bearing 3′-OH groups. These 3′-OH groups are the target for action of other enzymes that can add nucleotides via either template-dependent or nontemplate-directed mechanisms. The enzyme TdT adds bases to free 3′-OH groups in a nontemplate-directed manner, with a preference for guanine; these additional sequences are referred to as N regions. A second group of 'extra' nucleotides (i.e. bases not attributable to the germline V or J sequences) are the P nucleotides. These short stretches of up to four bases are palindromes of sequences at the end of coding joints and are thought to be generated by repair of overhanging ends during hairpin opening. Both N and P nucleotides contribute greatly to junctional diversity and, together with the inherent imprecision of V(D)J joining itself, are an important contribution to maximizing the possible range of antibodies that can be generated from a fixed number of germline mini-genes.

The final stage of VDJ recombination is the closing of the coding joint, and this proceeds by using the ubiquitously expressed enzymes involved in DNA repair and nonhomologous end joining (NHEJ). The key proteins involved are the XRCC4 protein in a complex with DNA ligase IV, as are the members of the Ku autoantigen family (Jeggo 1998). The overhanging ends of the opened hairpins will be repaired, either by exonuclease action to trim the ends or by polymerase action to fill the overhang with complementary nucleotides, before final joining of blunt ends. Any overhanging flaps that remain after trimming or in-filling are removed by flap endonucleases such as the fen endonuclease, or possibly by the RAG enzymes themselves. Ku binds exclusively to ends of DNA molecules in a sequence-independent manner; there are also no structural restrictions on Ku binding and so it can associate with blunt or overhanging ends (Smith and Jackson 1999). Binding of Ku allows other proteins to bind, including DNA-PKcs, and the XRCC4–DNA ligase IV complex and, indeed, Ku promotes the ligase activity of the latter complex (Jones et al. 2001). Recent structural analysis of Ku indicates that it can form a bridge over broken DNA in such a way that not only can it bind the free end of the DNA molecule (Walker et al. 2001; Jones et al. 2001), but it can also allow access of other proteins to the nucleotide strands to be joined and repaired. In V(D)J recombination, Ku is likely to serve to bind the blunt ends of the coding joints and recruit the XRCC4–DNA ligase IV complex to them (Ramsden and Gellert 1998; Nick McElhinny et al. 2000). It is the action of DNA ligase IV that ultimately forms the phosphodiester bond joining the V and J segments to yield a somatically recombined VJ unit.

A number of disease states provide compelling evidence for the involvement in the recombination process of the various proteins discussed above. Thus, there is ample evidence from knock-out mice that absence of *RAG-1* or *RAG-2* genes causes severe immunodeficiency usually manifest as a lack of both B and T cells, and the same is true of human RAG null mutations. However, RAG mutations that result in defective but not inactive proteins give rise to Omenn's syndrome (Villa et al. 1998), an immunodeficiency that is characterized by a lack of B cells and the presence of some T cells (Noordzij et al. 2000). As noted above, Artemis deficiency results in an unusual SCID disease (RS-SCID) and, intriguingly, the original *scid* mice accumulate unopened hairpin coding joints and rarely make coding joints (Roth et al. 1992); the defective gene in *scid* mice encodes DNA-PKcs (Schlissel 2002). Deficiencies in any of the Ku family proteins or in XRCC4 or DNA ligase IV all give rise to striking immunodeficiencies of differing levels of severity, usually coupled with defective DNA-repair and developmental abnormalities in a range of tissues. The data from disease states therefore underscore the importance of both lymphoid-specific and ubiquitous protein factors in V(D)J recombination.

Class switch recombination

Immunological memory in the humoral response is reflected in the production of higher affinity antibodies of non-IgM isotypes (e.g. IgG). The *Igh* locus comprises

the V, D, and J gene clusters, plus groups of exons encoding the individual domains of particular heavy chains (Figure 8). Increased affinity is a function of somatic hypermutation of V region sequences and selection of antigen-mediated selection of high affinity clones in germinal centers (see 'Antigen-dependent B-cell development' above). Isotype switching at the level of the DNA results from movement of the *VDJ* gene from its original position just 5′ to the Cμ gene to a new position immediately 5′ to, for example, the Cγ gene. All intervening DNA is deleted during this rearrangement process, called switch recombination, but the molecular signals are different from those controlling VDJ and VJ recombination events (Harriman et al. 1993; Kinoshita and Honjo 2001). The exception to this is the simultaneous production of mIgM and mIgD by mature B cells. The synthesis of the δ heavy chain does not involve switch recombination, but is a result of RNA splicing of a long transcript containing *VDJ*, all the Cμ information, and the Cδ gene (Blattner and Tucker 1984).

The 5′-flanking region of each C_H gene cluster contains a 'switch' recombination region (or S region). Unlike V(D)J recombination, there are no tightly defined DNA sequences for the S regions, although these areas do contain many tandemly repeated and palindromic sequences. As class switching always involves changing from synthesis of IgM (and IgD) to a second isotype located 3′ to the Cμ exons, it follows that Sμ is mandatory for pairing with downstream S regions of selected C_H exons. Indeed, deletion of the Sμ region greatly impairs class switching (Luby et al. 2001), and deletion of individual S regions blocks switching to the associated isotype (Gu et al. 1993; Jung et al. 1993; Kinoshita et al. 1998). As indicated in 'Antigen-dependent B-cell development', cytokines direct class switching and, at the molecular level, this is reflected in local alterations in chromatin structure. Thus, IL-4 promotes IgE synthesis and, in B cells undergoing such switching, IL-4 promotes synthesis of a sterile transcript comprising the Iε region plus the four Cε exons, indicative of a local opening of chromatin structure (Stavnezer-Nordgren and Sirlin 1986; Yancopoulos et al. 1986). Transcription is required for class switching to occur. Similarly, transforming growth factor β stimulation results in transcription of the Iα and Cα domains (Nakamura et al. 1996).

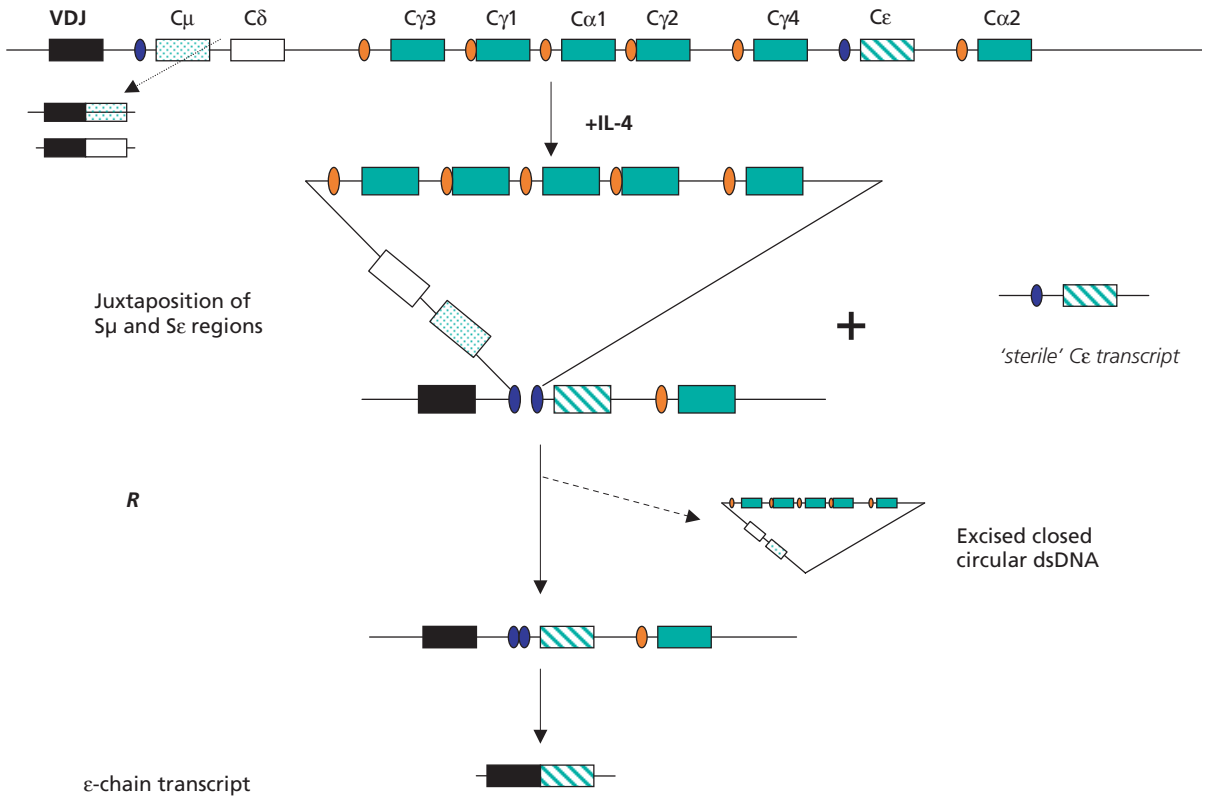

Figure 8 *Immunoglobulin isotype switching: the layout of the human* Igh *locus is shown and the S sequences at each* C_H *gene are illustrated as small red circles except those of Sμ and Sε which are blue. The figure depicts switching from IgM(D) synthesis (white and stippled boxes) to IgE production (hatched box) under the influence of interleukin 4 (IL-4) showing movement of the somatically recombined* VDJ *unit from 5′ of Cμ/Cδ to just 5′ of Cε, with concomitant loss of intervening DNA. Sterile and productive transcripts from the Ig locus during the isotype switch process are shown.*

Once the target C_H gene has been chosen (e.g. Cε), the Sμ and Sε regions are brought into close proximity so that the components of the recombination system can act. The putative switch recombinase cleaves the DNA, joins the S regions together (so bringing the *VDJ* unit close to the Cε exons), and removes the intervening DNA as a looped-out, closed, circular DNA (see Figure 8). The absence of defined 'switch recombination sequences' suggests that the recombinase machinery might recognize higher structural features of the DNA rather than sequence elements (Kinoshita et al. 1998; Tashiro et al. 2001). Current models suggest that the feature recognized is a single-stranded stem-loop structure not dissimilar to that recognized in V(D)J rearrangement. Such structures are favored by the presence of short inverted repeat sequences, such as those found in S regions.

Analysis of the junction regions in switch recombination products indicated the presence of both deletion of DNA sequences and duplication of others at the junctions (Lee et al. 1998; Kinoshita and Honjo 2001). These data indicate that the recombinase machinery introduces staggered cleavages or nicks into the two strands of DNA. Such staggered cleavage products could be acted on by either single-stranded nucleases or error-prone polymerases (e.g. TdT) to repair the ends before closure by the same NHEJ DNA-repair machinery that seals V(D)J joints.

Not only is transcription of the targeted C_H gene required for isotype switching, but *de novo* protein synthesis is also mandatory (Muramatsu et al. 1999), indicating the requirement for transcription and translation of new gene products during the switching process. One such gene is the AID product, whose expression is limited to B cells and, more importantly, to those B cells in germinal centers (Muramatsu et al. 1999). Over-expression of AID enhances class switching in in vitro models, and mice lacking the gene ($AID^{-/-}$) fail to produce IgG, IgA, or IgE, indicating that class switching has been abolished. Moreover, $AID^{-/-}$ animals show essentially no somatic hypermutation in response to immunization, suggesting that AID has a role in both class switching and somatic hypermutation. In humans, the hyper-IgM syndrome (HIM) manifests itself by over-production of IgM and a lack of other Ig isotypes. There are two forms of the disease HIM1: an X-linked condition linked to a failure to produce CD40L (Gordon and Pound 2000), and HIM2, an autosomal recessive condition mapping to 12p13, the location of the AID gene (Revy et al. 1998). $AID^{-/-}$ (Muramatsu et al. 2000) and HIM B cells (Revy et al. 2000) can perform VDJ recombination normally and, on cytokine stimulation, synthesize 'sterile' transcripts, suggesting that AID is required for the latter stages of switch recombination. This is entirely consistent with the cytidine deaminase activity of both murine and human AID (Muramatsu et al. 1999), a function that suggests a potential role for AID in RNA editing.

BcR heavy chains and Ig synthesis

Clonal selection requires the receptor Ig to have the same structure as the antibody that the B cell will later secrete. B cells simultaneously synthesize discrete mRNAs that program the synthesis of the structurally distinct receptor and secretory forms of their heavy chain polypeptide (Singer et al. 1980). This is again accomplished by RNA splicing, in this case by selective use of two small exons located at the 3′ end of the C gene for each heavy chain isotype, which encode hydrophobic sequences allowing stable insertion into the plasma membrane; these are the M (membrane) exons (Alt et al. 1980). Heavy and light chain mRNA molecules are synthesized on distinct membrane-bound polyribosomes and, in common with all secretory and membrane proteins, the nascent chains are guided across the endoplasmic reticulum membrane by a hydrophobic sequence, the signal peptide, which is proteolytically removed during transit across the membrane. Glycosylation of the nascent chain occurs co-translationally and assembly of four-chain units occurs in the lumen of the endoplasmic reticulum; in the case of IgM and IgA molecules, polymerization, and addition of J chains are late events, probably occurring immediately before the final secretory event. Ig synthesis proceeds in different B cells at distinct rates that reflect the state of differentiation of the B cell. Thus, a small resting B cell synthesizes 10^6 Ig molecules per day, mostly for use as receptor Ig, whereas a plasma cell can produce up to 2000 Ig molecules per second, essentially all of which is of the secretory form.

The active Ig gene is transcribed into a primary nuclear RNA (nRNA) transcript that contains not only the coding elements (exons) for V and C regions but also all the noncoding sequences (introns). Introns are found between the recombined VJ or VDJ unit and its appropriate C gene and, in the case of heavy chains only, between the exons that encode the individual domains of the heavy chain polypeptide. Introns are removed by RNA splicing to yield an mRNA molecule where all the V and C information is continuous. This is translated to yield the functional Ig polypeptide.

IMMUNOTECHNOLOGY: GENERATION AND USES OF MONOCLONAL ANTIBODIES

The specificity of antibodies makes them excellent tools for use in diagnostics and therapy. The critical advance that revolutionized the diagnostic and therapeutic application of antibodies was the development of MAbs (Kohler and Milstein 1975, 1976; Kohler et al. 1976). In short, this technology allows the establishment of an immortal cell line that secretes a single antibody of defined specificity. In practical terms, the procedure

exploits the enormous specificity present in a sample of normal lymphocytes and the capacity for infinite growth found in B-cell tumors.

In practice, normal lymphocytes from an immunized host are fused to continuously growing tumor cells in vitro to make a hybrid cell. The tumor cells are derived from plasmacytomas, a tumor of myeloma cells, and so have a highly developed secretory apparatus; sublines are generally chosen on the basis of an inability to synthesize their own heavy and light chains. As normal murine B lymphocytes are highly prone to apoptosis in vitro, any that do not fuse to the tumor cells die after a few days in culture. The tumor cells used in the fusion are chosen on the basis of a defect in nucleotide metabolism (a lack of the enzyme hypoxanthine–guanine phosphoribosyl transferase (HGPRT)), which means that addition of nucleotide analogues to the cultures will selectively cause death of the tumor cells. The normal lymphocytes possess HGPRT activity and when fused to a tumor cell contribute both their antibody specificity and their normal nucleotide metabolism to gain the immortal properties of the myeloma. It is this combination that allows only the hybrid cells to survive in the presence of the selecting drug. The hybrids, called 'hybridomas', can be cloned at limiting dilution and screened for the desired MAb specificity. Once a suitable clone is identified, it can be grown in large cultures, and gram quantities of homogeneous antibody produced.

Monoclonal antibodies have found many applications in medicine. Perhaps the most obvious example of an immunodiagnostic product is the pregnancy testing kit available at most pharmacists which employs MAbs to human chorionic gonadotropin (hCG) and yields a definitive result in under 5 min. In this system, MAbs to two distinct epitopes on the hCG molecule are generated, one for 'capture' and the second for detection. The capture MAb is immobilized on a plastic surface and binds any hCG present in a morning urine sample. In contemporary kits, the flow of fluid solubilizes the second MAb, directed against a distinct hCG epitope. This second MAb has an enzyme coupled to it that will convert a colorless substrate also present in the solubilized material into an insoluble product that precipitates around the zone where the first MAb is immobilized. In practice, this is visualized as a colored line. An insoluble precipitate can form only if the second MAb is retained in the 'sensor' area, an event that can occur only if hCG is itself captured by the first MAb. MAbs specific for a range of cell-surface markers are used in the diagnosis of leukemia (e.g. the presence of CD10, or c-ALLA, on cells derived from acute lymphoblastic leukemia patients, or the $CD5^+/CD23^+$ phenotype of B-chronic lymphocytic leukemia cells), and for accurate quantitation of analytes in tissue samples.

The application of MAbs in vivo as a therapeutic agent faces the hurdle of hypersensitivity reactions in the patient. Thus injection of murine Ig into an individual will provoke an anti-murine IgG response that will cause severe immune complex disease on subsequent exposure to the murine MAb (see Airway hypersensitivity and Autoimmunity). To overcome this, murine MAbs can be humanized by 'grafting' the CDRs from a useful murine MAb on to the backbone of a human IgG molecule. A similar strategy can be used to take useful sequences from antibody-combining sites selected by phage display methods, to generate a therapeutically useful product (e.g. the b12 IgG1κ molecular discussed earlier). These molecular manipulations go some way to alleviating the potential problems of host hypersensitivity, but this remains a significant factor in management of patients treated with MAbs.

Immunotherapeutics using antibodies envisages infusion of MAbs, either alone or coupled to radionuclides or potent biological toxins, as a means of eliminating tumor cells or alleviating other conditions (see Monoclonal antibody therapy). Several MAbs have met with notable success in the treatment of neoplastic and other diseases, although it is fair to note that the precise in vivo mechanisms by which they provide clinical benefit remain unclear. In allograft patients, a particular problem is rejection of the grafted tissue by host T cells. Two humanized MAbs, basiliximab and daclizumab, directed against the CD25 molecule (a component of high-affinity IL-2 receptors (Cushley et al. 2002)) have been used to suppress acute rejection in renal allograft patients (Waldmann 2000). The MAbs appear to function by blocking the capacity of IL-2 receptors to send mitogenic signals to host T cells, thereby blocking the early proliferative phase of the T-cell response to the allograft. Neither MAb elicits severe side effects in the patients, and daclizumab is notably effective when used in conjunction with immunosuppressive drugs such as cyclosporin. In the context of neoplasia, rituximab, an anti-CD20-specific reagent is widely used in treatment of non-Hodgkin's lymphoma and other B-cell neoplasias (McLaughlin 2002), with encouraging results. As the MAb appears to act by reducing (neoplastic) B-cell numbers, there are also suggestions that rituximab might be applied to eliminate or reduce the high levels of $CD20^+$ autoreactive B cells in patients with inflammatory autoimmune disease. Finally, in the specific case of rheumatoid arthritis, infliximab, an anti-tumor necrosis factor reagent, is used successfully to ameliorate disease, and finds application in other inflammatory disorders, including Crohn's disease (Graninger and Smolen 2002).

The B-cell antigen receptor

ANTHONY L. DEFRANCO

Structure and synthesis of the BCR	1	Functions of the BCR in B-cell maturation and activation	10
BCR signaling	4	Conclusion	11
BCR antigen uptake function	10	References	11

The major function of B lymphocytes is to make antibodies. The control of antibody production is a complex process, but a central element of that control, as initially enunciated by the clonal selection theory, is that contact of antigen by the B-cell antigen receptor (BCR) promotes activation of the B cell, which, if coming in the presence of sufficient additional signals such as those produced by helper T cells, leads to the production of antibodies.

Studies in recent years have revealed that the BCR plays a pervasive role in B-cell biology, driving nearly every step in the development of B-lineage cells into mature B cells, in addition to being a critical element in the triggering of B-cell activation. Also, the BCR plays a key role in promoting B-cell survival at several stages of B-cell life. These functions of the BCR are summarized in Figure 1.

STRUCTURE AND SYNTHESIS OF THE BCR

The BCR is a complex between the membrane form of immunoglobulin (mIg) and two signaling chains, called Igα and Igβ (or CD79a and CD79b) (Figure 2). Recognition of antigen by the mIg unit of the BCR leads to signaling via the cytoplasmic domains of Igα and Igβ.

The membrane and secreted forms of Ig made by a particular B cell differ only at the carboxy-terminal end of the heavy chain. This is achieved by differential transcriptional termination and RNA-processing events, giving rise to a distinct mRNA for each type of heavy chain. As a result, individual B cells have the same specificity in their antigen receptors and in the antibody that will be secreted after B-cell activation and terminal differentiation to the plasma cell state.

The mRNA encoding the secreted form of the heavy chain is made by usage of the first of two polyadenylation sites. Usage of this site occurs when transcription terminates before the two exons that encode the transmembrane and cytoplasmic exons. This early termination gives rise to an mRNA that encodes the secretory form, whereas usage of the second polyadenylation site permits RNA splicing which cuts out the sequence that is found only in the secretory form and also removes stop codons (Calame 2001). RNA splicing of this longer transcript produces mRNA encoding the membrane form of the heavy chain. The membrane forms of heavy chains contain at their carboxyl terminus a transmembrane domain and a very short cytoplasmic domain, ranging from 3 to 28 amino acids, depending on the isotype of heavy chain (Reth 1992). Whereas naïve B cells make primarily the membrane form of Ig, terminal differentiation of B cells into high rate antibody-secreting cells (plasma cells) leads to synthesis of much more of the secretory form and less of the membrane form, thereby leading to production of secreted antibodies.

Although the short (three amino acids) cytoplasmic domain of mIgM and mIgD is not known to have any function other than positioning the transmembrane domain relative to the membrane, the longer cytoplasmic domains of the switched isotypes could engage signaling components. In transgenic mouse experiments,

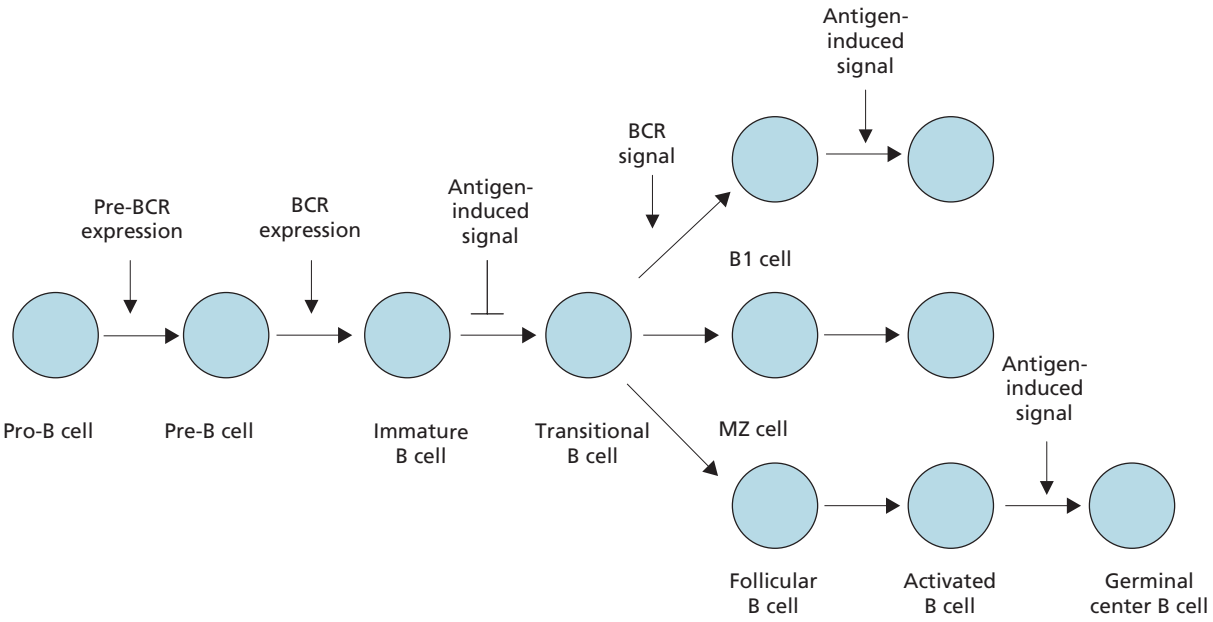

Figure 1 *Regulation of B-cell development, survival, tolerance, and activation by the B-cell antigen receptor (BCR). Shown are stages of B-cell development from the pro-B-cell stage (μ chain negative) to the three mature B cell types, B1 cells, marginal zone B cells and follicular B cells. Signals from the pre-BCR or BCR, either generated at a low level as a result of expression ('tonic' signaling) or induced by contact with a self or foreign antigen, regulate the steps shown. Arrows indicate stimulation of the step shown, whereas a perpendicular line indicates inhibition. Low-level BCR signals from weak responsiveness to self-antigens are probably required for maturation of all three B-cell types from transitional B cells, as well as their survival (not shown). Stronger BCR signals ('antigen-induced signal') promote activation of mature B cells, as well as entry of follicular B cells into germinal center reactions and survival of centrocytes.*

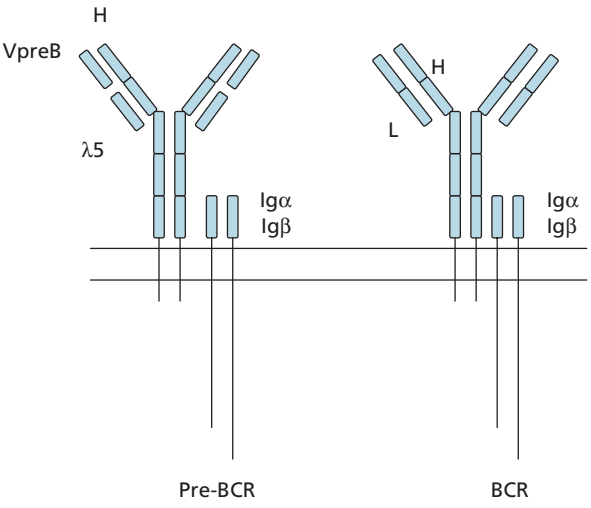

Figure 2 *Structure of the pre-BCR and the B-cell antigen receptor (BCR). The pre-BCR consists of a pair of identical μ heavy chains, each of which is bound to the two surrogate light chains, Vpre-B1 and λ5, and to a disulfide-linked heterodimer of Igα and Igβ. The cytoplasmic domains of these latter two molecules have ITAM sequences, which are primarily responsible for mediating signaling. The BCR is a similar structure, with rearranged κ or λ light chains instead of surrogate light chains. In mature B cells, BCRs with μ or δ heavy chains are found and isotype-switched B cells have BCRs with γ, α, or ε heavy chains complexed with light chains and Igα/Igβ.*

anti-lysozyme IgG1 transgenic mice were found to give rise to much larger T-cell-dependent antibody responses than equivalent IgM transgenic mice as a result of a greater proliferative burst and enhanced plasma cell differentiation. These properties could be conferred by the transmembrane domain plus the cytoplasmic tail of the γ1 heavy chain fused to the extracellular domain of the μ heavy chain (Martin and Goodnow 2002). It seems likely that this functional effect depends primarily on the cytoplasmic domains, because gene-targeted mice, in which there has been a deletion of the IgG1 cytoplasmic tail (Kaisho et al. 1997) or the IgE cytoplasmic tail (Achatz et al. 1997), show considerably decreased antibody production of those isotypes. Thus, the longer cytoplasmic tail of the isotype-switched Ig heavy chains promotes B-cell proliferation, survival, and antibody production and may account for the hallmark properties of memory B cells.

The pre-BCR and B-cell development

Pre-B cells have a signaling receptor related to the BCR called the pre-BCR. This receptor is a complex of Igα/Igβ, Ig heavy chain, and two polypeptides that take the place of light chain and hence are called surrogate light chains (see Figure 2). These two polypeptides, called λ5 and Vpre-B, each has an Ig domain related to light chain C and V regions, respectively. The pre-BCR plays

a critical role during B-cell development by generating a signal to indicate the presence of a properly rearranged heavy chain. When an IgH gene rearrangement occurs that creates an in-frame μ heavy chain gene, this leads to synthesis of Ig heavy chain and formation of the pre-BCR, which then sends a signal inducing further developmental progression toward the B-cell state (see Figure 1).

The function of the pre-BCR has been extensively studied by targeted gene mutations in mice (Kurosaki 2002a; Meffre et al. 2000). Ablation of the IgH locus or of the *rag1* or *rag2* genes required for V(D)J recombination causes a complete block in B-cell development in which $B220^+$ ($CD45R^+$) B-cell precursors fail to progress beyond the pro-B-cell stage, characterized as being positive for the S7 epitope of the CD43 molecule. This epitope is created by a specific carbohydrate modification of the CD43 polypeptide backbone (Shiota et al. 1994). Pro-B cells also have the functional property that they will proliferate in contact with suitable stromal cells derived from bone marrow, but will not proliferate in response to interleukin 7 (IL-7) in the absence of contact with stromal cells. Expression of a properly rearranged μ heavy chain and subsequent pre-BCR signaling induces enhanced responsiveness to IL-7 (Reichman-Fried et al. 1993; Fleming and Paige 2001). This developmental transition is also characterized by expression of CD25 (the α chain of the IL-2 receptor), and loss of expression of c-kit, a transmembrane tyrosine kinase receptor for a hemopoietic growth factor. Pre-BCR signaling also retargets the V(D)J recombinase away from the IgH locus and toward the IgL loci (Schlissel and Stanhope-Baker 1997). This is important for insuring that a given B cell expresses only a single Ig heavy chain, a phenomenon referred to as allelic exclusion.

Other mutations that affect pre-BCR assembly or signaling lead to impairment in the developmental transition from pro-B cell to pre-B cell (Figure 3). These include mutations of the IgH locus or of λ5, combined deletion of the cytoplasmic domains of Igα and Igβ (Kraus et al. 2001), and mutations in a variety of signaling components (Kurosaki 2002a; Meffre et al. 2000). The last mutations are discussed in greater detail below. Individual deletions of the cytoplasmic domain of Igα or Igβ have partial, but relatively mild, phenotypes, indicating a redundancy in the signaling capabilities of these two BCR-associated proteins.

BCR sequences that mediate intracellular signaling

The BCR complex forms in the endoplasmic reticulum, where mIg and Igα/Igβ subcomplexes are retained by chaperones until assembly occurs. Assembly allows the signaling-competent BCR to traffic to the cell surface. Igα and Igβ each contain an amino-terminal single Ig domain extracellular domain, a transmembrane domain,

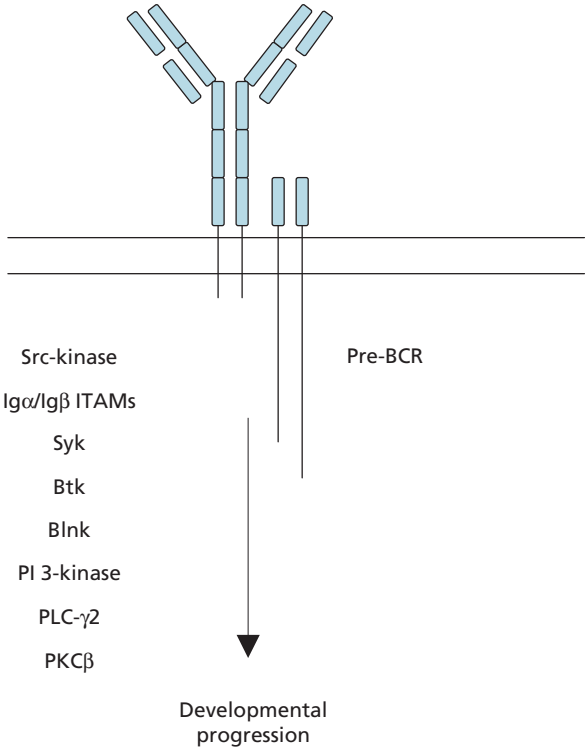

Figure 3 *Signaling events required for pre-BCR signaling. Genetic experiments have probed the signaling events required for the pre-BCR to induce developmental progression from the pro-B cell stage to the pre-B cell stage. Signaling components or sequences required for this transition are shown. In addition, μ heavy chain is required as is the λ5 surrogate light chain.*

and a moderate length cytoplasmic domain (about 50 amino acids long) containing immunoreceptor tyrosine-based activation motif (ITAM) sequences. ITAMs are found also in subunits of the T-cell receptor (TCR), the activating Fc receptors, and activating natural killer (NK) and myeloid cell receptors, and are responsible for the signaling functions of these receptors. Signaling is initiated by phosphorylation of the tyrosines in the ITAM motifs, as described in greater detail below. Targeted mutations of mice that mutate ITAM tyrosines of Igα or Igβ lead to defects in B-cell development, presumably as a result of defects in signaling by the pre-BCR and/or the BCR (Kraus et al. 2001; Kurosaki 2002a).

Higher order structure of the BCR

Recent studies have indicated that the BCR exists in the B-cell membrane as a higher oligomer of the basic $H_2L_2Ig\alpha/\beta$ unit (Schamel and Reth 2000; Matsuuchi and Gold 2001; Reth 2001). The number of units within these higher-order structures has not been defined, but unliganded BCR complexes are submicroscopic and thus are probably relatively small oligomers. These oligomers are composed of single isotypes of mIg (e.g. individual oligomers contain all mIgM or all mIgD on a naïve B cell expressing both IgM and IgD).

The functional consequence of the oligomeric structure of the BCR has likewise not been clearly defined, but there are two leading hypotheses. The first is that these oligomers hold the BCR in a conformation that sends a tonic signal which promotes B-cell developmental events and survival of mature B-cell types (see Figure 1) (Reth 2001). According to this hypothesis, antigen binding distorts these oligomers and thereby results in a qualitative change in the nature of BCR signaling events. This qualitatively different BCR signal would promote activation of mature B cells or deletion of transitional B cells. The clearest precedent for this model is distortion of IgM pentamers on antigen binding which initiates the complement cascade. However, at this point there is little evidence for two qualitatively distinct modes of BCR signaling.

The alternate hypothesis also holds that, in the absence of antigen, there is a low level of tonic BCR signaling which mediates various developmental transitions and survival of mature B cells. However, this hypothesis postulates that antigen induces clustering of BCRs, which triggers a higher level of the same signaling events. The latter hypothesis has been the more traditional view of how BCR signaling is triggered and in general can explain many of the phenomena regarding the relationship between the oligomeric state of antigens and their ability to induce stronger or weaker immune responses, e.g. antigens able to crosslink the BCR strongly (e.g. capsular polysaccharides of bacteria and capsid proteins of highly ordered virus particles (Mond et al. 1995; Bachmann and Zinkernagel 1996)), can induce antibody responses in the absence of helper T cells, whereas most protein antigens, which have a lesser potential for inducing BCR clustering, require T-cell help to generate an antibody response.

The clustering hypothesis is compatible with the idea that the BCR pre-exists in higher-order oligomers, although clearly it does raise questions about why the oligomers signal at only a low rate, whereas further clustering triggers a much higher amount of signaling. This issue may relate to lipid raft localization, which is triggered by clustering of the BCR with a ligand (see below). Moreover, given the complexity of BCR signaling events (DeFranco 1997; Kurosaki 2002b) and the observations that some signaling events participate in some biological responses to the BCR and not others (Richards et al. 2001), it may be that tonic signaling generates a subset of the signaling reactions induced by antigen-induced clustering, e.g. the signals may have some qualitative differences in addition to quantitative differences.

According to the clustering hypothesis for BCR signaling, what is the purpose of the higher-order oligomeric structure of the BCR before antigen encounter? It is likely that clustering of oligomers instead of monomeric BCR units ($H_2L_2Ig\alpha/\beta$) would amplify the signal at low doses of antigen as clustering would bring together oligomers, each with multiple Igα/β signaling modules (Matsuuchi and Gold 2001). Indeed direct evidence for this possibility has been obtained in experiments using coexpression of two distinguishable forms of Igα, one of which had an external FLAG-epitope tag (Schamel and Reth 2000). Stimulating only the FLAG-tagged BCRs by using an anti-FLAG antibody revealed tyrosine phosphorylation not only of the FLAG-tagged Igα molecules, but also of the untagged Igα molecules. Presumably this is because oligomers contain both types of Igα molecules. Thus, BCRs that are not directly bound by the stimulating antibody are activated to signal.

BCR SIGNALING

Antigen-induced clustering of the BCR leads to rapid tyrosine phosphorylation of the ITAM tyrosines by the Src family tyrosine kinases expressed in B cells, Lyn, Fyn, and Blk. Why this occurs is not clearly established, but it may relate to the microdomains of the plasma membrane referred to as lipid rafts. Lipid rafts are enriched in cholesterol, sphingolipids, and a variety of lipid-modified proteins, all of which associate with one another in a dynamic fashion to form subdomains that vary in size from about 70 nm in diameter to almost 1 μm (Pierce 2002). In unstimulated B cells, these structures are relatively small and dispersed, although they may account for as much as 30 percent of the plasma membrane surface area. Lyn, Fyn and Blk are highly enriched in lipid rafts, whereas before stimulation the BCR is found in the nonraft region of the bilayer. Upon stimulation, the BCR rapidly enters or associates with lipid rafts, and this association apparently does not require phosphorylation of the ITAMs of the BCR (Cheng et al. 2001).

Why antigen-induced multimerization of the BCR induces it to associate with lipid rafts is not known. One hypothesis is that the BCR has a weak affinity for lipid rafts as an oligomer, and multimerization increases that interaction, making it more stable. An argument against this possibility is that the association of antigen-ligated BCRs with lipid rafts occurs in mature B cells but not in immature B cells (Sproul et al. 2000; Chung et al. 2001), suggesting that there is some way of regulating this association. A second hypothesis is that a small subset of BCR molecules are preassociated with lipid rafts and multimerization brings non-lipid draft BCRs together with raft BCRs, with the resulting aggregate now associated with rafts. In this case, a regulated post-translational modification or protein–protein association could be responsible for directing some BCRs to lipid rafts before stimulation.

Activation of protein tyrosine kinases by the BCR

A major consequence of BCR association with lipid rafts is likely to be a closer proximity of the BCR and Src

family tyrosine kinases located in the lipid rafts and hence increased tyrosine phosphorylation of the ITAMs. Phosphorylation of both tyrosines of a single ITAM triggers the binding of a second type of intracellular protein tyrosine kinase, Syk (Figure 4). This binding is mediated by association of the two SH2 (Src homology 2) domains of Syk with the doubly phosphorylated ITAM sequence. The ITAM sequence is essentially a tandem SH2-binding site, with the amino acids between the two SH2-binding motifs (Y-PxxL/I where Y-P means a phosphorylated tyrosine) extending a sufficient distance to permit the ITAM to bind simultaneously to both SH2 domains of one Syk molecule, as demonstrated by structural studies (Futterer et al. 1998).

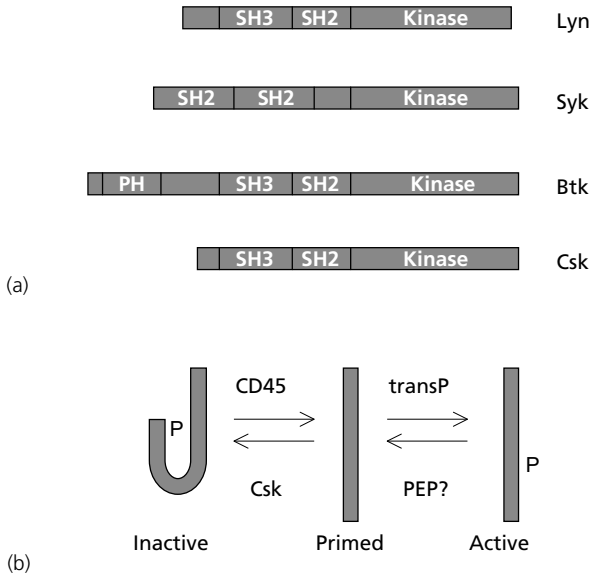

Figure 4 *Tyrosine kinases involved in B-cell antigen receptor (BCR) signaling.* **(a)** *Structures of the four major types of intracellular protein tyrosine kinases that participate in or regulate BCR signaling. Lyn, Fyn, and Blk are members of the Src family of tyrosine kinases, which have amino-terminal unique sequences with lipid attachment sites (myristate in all cases and palmitate in the cases of Lyn and Fyn). The unique region is followed by Src homology 3 (SH3) and Src homology 2 (SH2) domains, a kinase domain, and a negative regulatory tyrosine near the carboxyl terminus (not shown). Syk, like ZAP-70 has two SH2 domains, an interdomain region with sites of regulatory tyrosine phosphorylation, and a kinase domain. Btk, a Tec family kinase, has an amino-terminal pleckstrin homology (PH) domain that mediates regulated binding to membranes via PIP_3, followed by SH3, SH2, and kinase domains. Csk is responsible for phosphorylating the negative-regulatory site on Src family kinases and has a structure similar to Src, but lacking the amino-terminal fatty acylation sites and the negative regulatory tyrosine.* **(b)** *Regulation of Src family tyrosine kinases by tyrosine phosphorylation. Csk phosphorylation of the carboxy-terminal negative regulatory site of Lyn converts it to an inactive state in which the SH2 domain is bound to the C-terminal tyrosine phosphate and the kinase domain is inactive. CD45 is responsible for removing the carboxy-terminal tyrosine phosphate. Lyn lacking the carboxy-terminal phosphate is in a primed but low activity state. Transphosphorylation of a tyrosine residue in the activation loop of the kinase domain leads to the fully active state. The tyrosine kinase PEP is a leading candidate for removing this activating phosphorylation and it forms a complex with Csk, suggesting coordinate regulation converting active Src family kinases to the inactive state. This inactivation may occur via a feedback inhibition mechanism, because Src family kinases apparently are responsible for phosphorylating Cbp, which recruits Csk to the membrane.*

Once Syk has docked on to the oligomerized BCRs in the lipid rafts, it becomes activated. The binding of an ITAM to the Syk SH2 domains appears to be partly responsible for this activation by allosteric means (Rowley et al. 1995; Shiue et al. 1995). In addition, Syk is activated by tyrosine phosphorylation of a tyrosine in the kinase domain activation loop (Kurosaki et al. 1995). Syk activity appears to increase by at least 10-fold and, of course, Syk activity is also localized by its association with the BCR. Indeed, fluorescence microscopy demonstrates a dramatic movement of Syk from the cytosol to the plasma membrane after BCR crosslinking (Ma et al. 2001), and this association is primarily associated with lipid raft subdomains of the plasma membrane (Gupta and DeFranco 2003). Similarly, a dramatic increase in tyrosine phosphorylation of proteins can also be seen to occur coincident with lipid raft microdomains. Thus, BCR signaling appears to be occurring primarily in or adjacent to lipid rafts.

In addition to the activation of Syk, there is also a rapid increase in the activity of Src family tyrosine kinases on stimulation of the BCR (Saouaf et al. 1994). This increase may result partly from association of Src family tyrosine kinases with ITAM half-sites via their single SH2 domains (Law et al. 1993; Clark et al. 1994). Alternatively, it may relate to decreased inhibition of Src kinase activity by Csk, which phosphorylates the C-terminal negative regulatory tyrosine of Src family kinases (Figure 4). Csk localization is regulated and, in T cells, Csk is present initially in lipid rafts bound to a protein called Csk-binding protein (Cbp) (also called PAG). Upon TCR stimulation, Csk is released from Cbp by dephosphorylation of Cbp (Torgersen et al. 2001). Whether or not this occurs in B cells is not yet known. Finally, greater removal of Csk phosphorylations by the transmembrane protein tyrosine phosphatase CD45 could be an important means of regulating activity of Src family tyrosine kinases (Figure 4).

Formation of signaling complexes

Once Syk is activated, it phosphorylates the key signaling adapter molecule BLNK (also called SLP-65) (Kelly and Chan 2000; Kurosaki 2002b). BLNK is a cytosolic molecule containing a carboxy-terminal SH2-domain and multiple tyrosines that become phosphorylated and then serve as binding sites for SH2-containing signaling molecules (Fu et al. 1998). How BLNK is localized to signaling receptors is not entirely clear at this point. In TCR signaling, the adapter SLP-76 is

closely analogous to BLNK and it is recruited to participate in TCR signaling by binding to a phosphorylated tyrosine in a transmembrane lipid raft-localized protein called linker for activation of T cells (LAT). Genetic evidence demonstrates that both SLP-76 and LAT are required for TCR signaling (Leo and Schraven 2001). Moreover, SLP-76 and LAT, but not either molecule alone, can replace BLNK to permit BCR signaling in DT-40 chicken B cells mutated in BLNK (Wong et al. 2000). These observations suggest that there may be a B-cell-specific equivalent of LAT and a candidate molecule called LAB (linker for activation of B cells) or NTAL (non T-cell activation linker) has been found (Brdicka et al. 2002; Janssen et al. 2003). An alternative possibility is that the BCR itself recruits BLNK to participate in BCR signaling and indeed there is evidence that BLNK's SH2 domain can bind well to a non-ITAM tyrosine (Y204) of Igα when this tyrosine becomes phosphorylated (Engels et al. 2001; Kabak et al. 2002).

The importance of BLNK for BCR signaling has been established by genetic experiments in chickens (Fu et al. 1998) and mice (Pappu et al. 1999; Hayashi et al. 2000; Xu et al. 2000), and by the discovery of rare immunodeficiency patients with agammaglobulinemia who have loss of function mutations of BLNK (Minegishi et al. 1999). Mice lacking BLNK have a strong block in B-cell development at the pro-B cell stage, probably as a result of a defect in pre-BCR signaling. An equivalent defect is seen in mice with genetic ablation of Syk (Cheng et al. 1995; Turner et al. 1995) or of the three main Src family tyrosine kinases expressed in B cells (Lyn, Fyn, and Blk) (Saijo et al. 2003) (see Figure 3).

Phosphorylation of BLNK leads to formation of a signaling complex that includes a third type of intracellular protein tyrosine kinase, Btk (see Figure 4), and phospholipase Cγ2 (PLCγ2) (Kurosaki 2002b). In this complex, Btk becomes activated, apparently by phosphorylation by Syk, whereupon it phosphorylates PLCγ2, activating its catalytic function. Thus, BLNK both recruits PLCγ2 to the membrane where its substrate phosphatidylinositol 4,5-bisphosphate (PIP_2) is located and promotes its activation (Figure 5). These combined actions induce PLCγ2 to hydrolyze PIP_2, yielding diacylglycerol, which activates protein kinase C

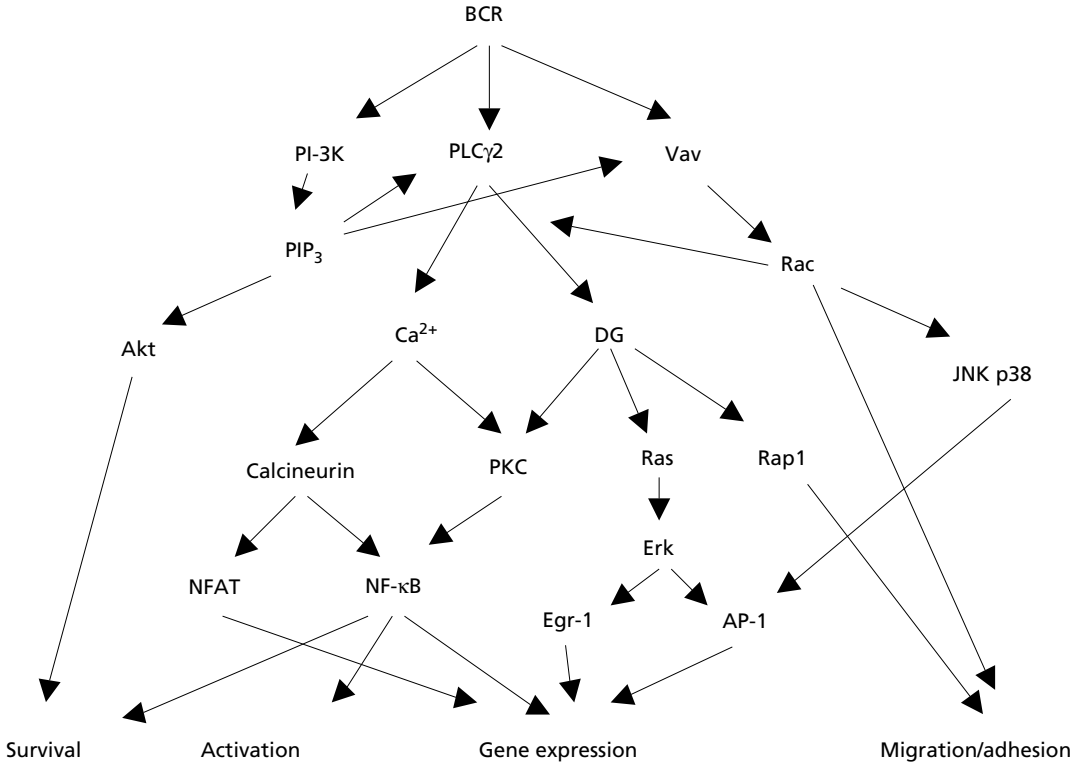

Figure 5 *Networks of signaling reactions activated by the B-cell antigen receptor (BCR). Clustering of the BCR causes it to associate with lipid rafts, which contain Lyn, Fyn and Blk. These Src family tyrosine kinases phosphorylate the BCR ITAMs, inducing recruitment of Syk (not shown), with each of its SH2 domains binding to one-half of the phosphorylated ITAM. Activated Syk and/or Src family tyrosine kinases phosphorylate adapter molecules (see text) such as Blnk and BCAP, leading to activation of PI 3-kinase, PLC-γ2 and the guanine nucleotide exchange factor Vav. PIP_3 generated by PI 3-kinase plays an important role in activation of PLC-γ2 and Vav, as well as the protein kinase Akt, which promotes survival. PLC-γ2 hydrolyzes the phospholipid PIP_2, generating calcium and diacylglycerol (DG). These reactions lead to activation of the transcription factors NFAT, NF-κB, and AP-1 and the induced expression of the transcription factor Egr-1. Also activated are the small-molecular-mass GTP-binding proteins Ras, Rac, and Rap1, which regulate gene expression via MAP kinases and also regulate actin networks and integrin adhesiveness, controlling adhesion, and migration.*

(PKC) isoforms, and inositol 1,4,5-trisphosphate (IP_3), which opens channels releasing stored calcium into the cytoplasm. Depletion of intracellular calcium stores results in the opening of plasma membrane Trp1 channels to keep intracellular free calcium levels elevated (Mori et al. 2002).

The recruitment of Btk to the plasma membrane requires not only BLNK but also phosphoinositide 3-kinase (PI 3-kinase) (Kurosaki 2002b). PI 3-kinase phosphorylates PIP_2 to yield phosphatidylinositol 3,4,5-trisphosphate (PIP_3). PIP_3 in turn provides a binding ligand for Btk. Thus, Btk is recruited to participate in BCR signaling by the combined action of BLNK and PI 3-kinase.

Btk and a number of other signaling proteins are attracted to the membrane by PIP_3 via homologous domains, called pleckstrin homology (PH) domains. Among these PH domain- containing signaling proteins are the protein kinase Akt and its upstream activating kinase PDK-1. Akt is thought to be important for promoting B-cell survival.

Mice or humans with mutations in Btk, the PI 3-kinase p85α subunit, or PLCγ2 exhibit impairment in B-cell development that is similar to that seen in the Blnk and Syk deficiencies (Fruman et al. 2000), presumably reflecting the participation of these components in pre-BCR signaling (see Figure 3).

Activation of PI 3-kinase

Activation of PI 3-kinase by the BCR is also mediated by adapter proteins. On BCR oligomerization, the transmembrane protein CD19 becomes phosphorylated on tyrosines in its cytoplasmic domain which serve as recruitment sites for PI 3-kinase and another signaling molecule Vav (see below) (Kelly and Chan 2000). CD19 is part of the complement receptor 2 (CR2) complex and acts as a co-receptor for BCR signaling, as discussed below.

A genetic deficiency in CD19 in mice compromises BCR signaling (Engel et al. 1995; Rickert et al. 1995), although less so than mutation of PI 3-kinase or Btk, suggesting that there are other mechanisms for activating PI 3-kinase. Two other adapter proteins have been found to bind PI 3-kinase after BCR stimulation: B-cell adapter for PI 3-kinase (BCAP) (Okada et al. 2000) and Grb-2-associated binding protein 1 (Gab1) (Ingham et al. 2001). PI 3-kinase activation is compromised in BCAP mutants of the chicken DT-40 B-cell line (Okada et al. 2000), but not in splenic B cells from mice lacking BCAP. These mice do exhibit defects in B1 B-cell development, greatly decreased antibody responses to T-independent type II antigens (see below), and somewhat decreased numbers of mature B cells (Yamazaki et al. 2002). Moreover, the BCAP-deficient B cells have poor calcium elevation and poor proliferative responses, although decreased activation of PI 3-kinase was not evident (Yamazaki et al. 2002). These defects are less than those seen in PI 3-kinase p85α subunit or Btk mutant mice. It could be that CD19 and BCAP represent independent routes for BCR-induced activation of PI 3-kinase, or alternately that they act in concert or that BCAP functions for activation of PLC-γ2 independently of PI 3-kinase.

BCR signaling induces phosphorylation of Gab1 along with binding of PI 3-kinase. So far, the effects of removing Gab1 on B-cell function have not been established, but overexpression of Gab1 in the WEHI-231 B-cell line potentiated BCR-induced activation of PI 3-kinase (Ingham et al. 2001). BCR stimulation induces Gab1 translocation from the cytosol to the plasma membrane and this translocation requires the PH domain of Gab1, which binds PIP_3. Therefore it has been proposed that Gab1 is an amplifier of PI 3-kinase activation in BCR signaling. Initial activation of PI 3-kinase via CD19 or BCAP is postulated to result in production of some PIP_3, which would attract Gab1 to the membrane, where it would become tyrosine phosphorylated and recruit additional PI 3-kinase (Ingham et al. 2001).

Signaling events activated by the BCR

As described above, BCR stimulation leads to activation of PI 3-kinase and PIP_2 hydrolysis. BCR stimulation also leads to activation of Vav1, Vav2, and Vav3, which are exchange factors for Rac/Rho family GTPases, activation of Ras, and downstream activation of a variety of transcription factors, including NFAT, NF-κB, AP-1, and Egr-1 (DeFranco 1997; Kurosaki 2002b).

VAV

Vav exists as three isoforms: Vav1, Vav2, and Vav3. Genetic experiments have demonstrated the importance of Vav1 and Vav2 in murine B cells (DeFranco 2001) and Vav3 in DT-40 chicken B cells (Inabe et al. 2002). Vav1 is thought to be activated as a consequence of its recruitment either to the cytoplasmic tail of CD19 or to BLNK, in either case via an SH2-mediated interaction. How Vav2 and Vav3 are activated is less clear. Deficiency of Vav1 in mice leads to loss of B1 B cells, as does loss of CD19, whereas Vav2-deficient mice have decreased T-cell-independent type 2 and T-cell-dependent antibody responses. These findings indicate that Vav1 and Vav2 have distinctive functions (DeFranco 2001). The Vav1/Vav2 double knockout mice have severe defects in B-cell development, maturation in the periphery, and BCR signaling, indicating that many of the functions of Vav1 and Vav2 are overlapping.

The three Vavs all function as activators of Rac family GTPases. Among the downstream consequences of Vav activation are modest activation of the JNK and p38 mitogen-activated protein (MAP) kinases, stimulated

actin polymerization, and activation of PIP 5-kinase, which replenishes PIP_2 to permit rapid PIP_2 hydrolysis by PLCγ2. Indeed *vav1*$^{-/-}$*vav2*$^{-/-}$ B cells exhibit very poor calcium responses to BCR stimulation, indicating weak PIP_2 hydrolysis (DeFranco 2001). Vav3 has been reported to activate PI 3-kinase in chicken B cells downstream of activation of Rac1 (Inabe et al. 2002). As Vav has a PH domain that binds to PIP_3 resulting in increased activity for activation of Rac, it may be that Vav activation of PI 3-kinase is part of a positive feedback amplification loop (Kurosaki 2002b).

RAS

Another key signaling reaction activated by the BCR involves the small GTPase Ras. BCR signaling promotes the loading of GTP on to Ras, which converts it to the active configuration (DeFranco 1997; Gold 2002). Activated Ras has a number of different downstream effects, but the best characterized is the activation of the Erk MAP kinases. MAP kinases are involved in activation of a number of transcriptional pathways.

The mechanism by which the BCR activates Ras is not well established. A major mechanism for the activation of Ras by many receptors involves tyrosine phosphorylation of binding sites for the adapter molecule Grb2, either on a receptor or on the adapter molecule Shc. In most cells, Grb2 is pre-bound to Sos, a guanine nucleotide exchange factor for Ras. Recruitment of Sos to the plasma membrane brings it in close proximity to Ras, where it can induce Ras to release GDP and bind GTP. In lymphocytes, however, Grb2 and Sos are not present in a complex before stimulation (Ravichandran et al. 1995; Harmer and DeFranco 1997). BCR stimulation induces a large increase in Shc phosphorylation and there is formation of a Shc/Grb2/Sos complex, which is localized to the plasma membrane (Saxton et al. 1994; Harmer and DeFranco 1997).

Given the important role of Grb2 and Sos in activating Ras in other systems and the strong tyrosine phosphorylation of Shc in response to BCR stimulation, it has been attractive to consider this to be the mechanism by which BCR stimulation leads to Ras activation. However, genetic studies in DT-40 chicken B cells have found that Grb2 and Shc are not necessary for the activation of Ras via the BCR (Nagai et al. 1995). Thus, the importance of Shc for BCR signaling remains unclear. Interestingly, most of the phosphorylated Shc in BCR-stimulated B cells is in a complex with SHIP (Harmer and DeFranco 1999), an SH2-domain containing inositol phosphatase which is active in removing the 5-phosphate from PIP_3, and thereby countering at least some of the actions of PI 3-kinase (see below), so Shc's primary role may reflect feedback inhibitory events rather than Ras pathway activation.

Recently, a second mechanism for activating Ras in some cell types has been established. Diacylglycerol generated from PIP_2 breakdown can recruit a distinct type of guanine nucleotide exchange factor for Ras, called RasGRP (Ebinu et al. 2000). In this activation mode, Ras activation is downstream of PIP_2 hydrolysis. This possible mechanism for BCR activation of Ras is supported by studies in DT-40 cells, which have shown the importance of phospholipase (PLC)γ2 for activation of the Ras pathway (Hashimoto et al. 1998), a result that would not be expected if Shc/Grb2/Sos were responsible for BCR-induced Ras activation.

In addition to Ras, Rac family GTPases are also activated by the BCR, as indicated by Vav activation (Hashimoto et al. 1998). Rac family GTPases regulate actin polymerization and activation of JNK and p38 MAP kinases, as described above.

A third type of small GTPase that is activated by BCR signaling is Rap1 (McLeod et al. 1998). Activated Rap1 increases integrin binding to their ligands and thereby promotes cell adhesion and possibly migration (Gold 2002). Activation of Rap is thought to be a consequence of diacylglycerol elevation resulting from PLC-γ2 activation.

Activation of transcription factors downstream of BCR signaling

A key signaling pathway downstream of the BCR is the activation of the NF-κB transcription factors, which are dimers of two types of subunits: the p50 (p50 or p52) and the p65 type (p65/RelA, c-Rel, or RelB). Mice deficient in the c-Rel and p50 subunits of NF-κB have normal lymphocyte development but are severely defective in B- and T-cell activation (Pohl et al. 2002). Thus, antigen receptor activation of NF-κB is necessary for lymphocyte activation. How antigen receptors activate NF-κB is not well established, but some of the players are known. In T cells, PKCθ is required for TCR activation of NF-κB (Arendt et al. 2002). The analogous function in B cells is performed by PKCβ (Saijo et al. 2002; Su et al. 2002).

Another signaling component that has been found to participate in antigen receptor activation of NF-κB is the adapter molecule Bcl-10. Mice lacking Bcl-10 have a lymphocyte phenotype that is very similar to that of NF-κB knockouts: normal lymphocyte development, but a failure of lymphocyte activation (Ruland et al. 2001). Bcl-10 is an adapter molecule with an amino-terminal domain with considerable homology to caspase recruitment domains (CARD) of other proteins such as Apaf-1. Bcl-10 was initially discovered as being encoded by a gene translocated to the Ig locus in a subset of B-cell lymphomas (Willis et al. 1999), so overexpression of Bcl-10 probably contributes to lymphoma formation. The opposite hypothesis has also been advanced, e.g. that translocation to the Ig locus leads to inactivation of Bcl-10 by somatic mutation (Willis et al. 1999), but

translocations are not always accompanied by somatic mutations in Bcl-10, so the model that Bcl-10 overexpression contributes to lymphoma formation, probably via activation of NF-κB, seems most likely.

Bcl-10 is thought to function in a complex with CARD11 (also called CARMA1) or related proteins containing CARD, PDZ, SH3, and guanylate kinase domains (Pomerantz et al. 2002). In addition to CARD11, which is highly expressed in lymphoid tissues, this subgroup of the membrane-associated guanylate kinase (MAGUK) family of molecular scaffolds includes CARD10 (Bimp1), and CARD14 (Bimp2) (Bertin et al. 2000, 2001; Gaide et al. 2001, 2002; McAllister-Lucas et al. 2001; Wang et al. 2001). Other members of this signaling complex are less well defined, but may include a protein with caspase-like, Ig-like, and death domains called mucosa-associated lymphoid tissue 1 (MALT-1) (Akagi et al. 1999; Morgan et al. 1999). The gene for MALT-1, similar to that for Bcl-10, is translocated to the Ig loci in a subset of MALT lymphomas.

As in T cells, elevation of intracellular calcium resulting from BCR engagement leads to activation of NFAT transcription factors (Dolmetsch et al. 1997), although their downstream targets in B cells are not well characterized. One target appears to be the gene encoding CD5 (Berland and Wortis 1998), which is a negative regulator of BCR signaling (see below). Curiously, mice genetically modified to ablate both NFATc1 and NFATc2 have hyperactivated B cells and elevated levels of IgG1 and IgE (Peng et al. 2001). NFATc2 ablation alone resulted in increased B-cell proliferation (Caetano et al. 2002).

Ets transcription factors such as Ets-1 are also likely to be regulated by calcium elevation in B cells (Fisher et al. 1991); in the case of Ets-1, calcium leads to its inactivation. Mice in which the Ets-1 gene has been ablated exhibit elevated numbers of IgM-secreting plasma cells (Bories et al. 1995), indicating that Ets-1 probably plays a role in maintaining B cells in a resting state in the absence of antigenic stimulation. Two other Ets family transcription factors important in B cells are PU.1 and Spi-B (Su et al. 1997), apparently by regulating expression of c-Rel, a NF-κB family member (Hu et al. 2001).

Another transcription factor that plays an important role in mediating the response to BCR signaling is Egr-1, which is an early response gene that is activated via the Ras pathway and serum response element (SRE) sequences in B cells (McMahon and Monroe 1995). Downstream of Egr-1 appear genes encoding two cell adhesion molecules, ICAM-1 and CD44 (Maltzman and Monroe 1996b, 1996a). MEK (or MAP kinase/ERK kinase) inhibitors, which block the Ras/Erk pathway just upstream of Erk, block activation of Egr-1, upregulation of these adhesion molecules, and B-cell proliferation induced by BCR signaling (Richards et al. 2001).

B-cell co-receptors

The concept of co-receptors was initially developed to describe the role of CD4 and CD8 in T-cell activation. Both the TCR and the co-receptors bind to the same ligands, MHC–peptide complexes. Clustering of TCR and co-receptor by binding to the same ligand allows their cytoplasmic domains to cooperate to generate stronger TCR signaling reactions than would occur without the co-receptor. Thus, one can view the role of the co-receptor as providing additional information about the ligand that is being recognized by the TCR. B cells also have co-receptors which provide important additional information about the nature of molecules that bind to the BCR or the type of cell on which the antigen is found.

The CR2 (also called CD21) complex is a positively acting co-receptor for B cells. CR2 forms a complex with CD19 and CD81. If complement fragments are deposited on an antigen, then the antigen is much more effective at inducing an immune response, as a result of the ability of the CR2/CD19/CD81 complex to boost suboptimal BCR signaling, e.g. immunization of mice with a lysozyme fusion protein containing ligands for CR2 allowed it to elicit a strong antibody response at 1000–10 000 × lower concentration of immunizing antigen compared with normal lysozyme (Dempsey et al. 1996). This enhanced B cell activation is thought to result from phosphorylation of the cytoplasmic tail of CD19 on sites that permit recruitment of Vav and PI 3-kinase, two signaling components described above (Fearon and Carroll 2000). CD19 also binds to Lyn and promotes its activation (Fujimoto et al. 2000); it helps maintain the BCR in lipid rafts (Cherukuri et al. 2001b) and enhances loading of antigenic peptides on to class II MHC molecules for antigen presentation to T cells (Cherukuri et al. 2001a).

B cells also express several co-receptors that decrease B-cell activation, analogous to the regulation of NK cell killing by NK cell inhibitory receptors. The best understood example is FcγRIIB. Co-engagement of the BCR and FcγRIIB blocks B-cell activation when a naïve B cell encounters antigen in the form of immune complexes with IgG. This is a circumstance when an immune response has already been made, so FcγRIIB mediates a negative feedback loop, and indeed mice lacking FcγRIIB exhibit enhanced antibody responses, particularly at later times (Takai et al. 1996). The inhibitory function of FcγRIIB is circumvented when a germinal center B cell contacts antigen on the surface of a follicular dendritic cell, probably because these cells have a very high density of FcγRIIB and therefore bind the Fc portions of the IgG in the immune complexes on their surface (Tarlinton and Smith 2000).

The inhibitory effect of co-engagement of FcγRIIB with the BCR is the result of a sequence motif in the

cytoplasmic domain of FcγRIIB, called the immunoreceptor tyrosine-based inhibitory motif (ITIM), consisting of I/V/L/SxYxxL/V. When FcγRIIB and the BCR are brought together by an IgG-containing immune complex, kinases associated with the BCR, of which Lyn is the most important (DeFranco et al. 1998), phosphorylate the tyrosine in the FcγRIIB ITIM. This phosphorylation serves as a site to recruit SHIP, a phosphatase that removes the 5-phosphate from PIP_3, and thereby counters the positive action of PI 3-kinase for B-cell activation (Ono et al. 1997; Kurosaki 2002b). SHIP also forms a complex with $p62^{dok}$ and RasGAP, so it appears also directly to downregulate Ras activation. Indeed, mice lacking $p62^{dok}$ fail to suppress Erk activation (Tamir et al. 2000; Yamanashi et al. 2000).

A second established negative co-receptor of B cells is CD22, which is an Ig superfamily member specific for some sialic acid-containing glycoproteins, and thus a member of the family of proteins called Siglecs (Tsubata 1999; Crocker and Varki 2001). Although the role of CD22 in regulating B-cell activation is not well understood, it has been proposed that it inhibits BCR signaling when the B cell recognizes an antigen on the surface of a host cell, rather than on the surface of a microbe that does not express sialic acid (Lanoue et al. 2002).

Other inhibitory receptors on B cells include PIR-B, CD72, and CD5 (expressed by B1 cells and anergic B cells), although their functions remain to be elucidated.

BCR ANTIGEN UPTAKE FUNCTION

The BCR, in addition to its signaling function, also plays a key role in B-cell activation by its function as an uptake receptor, greatly increasing the amount of antigen presented by B cells that can bind the antigen via their BCR versus B cells that cannot. This antigen is routed to the correct intracellular compartment, e.g. the late endosomes, where it is processed to peptides and loaded on to MHC class II molecules. Therefore, the efficient uptake and presentation of antigen allow antigen-specific B cells to present that antigen to helper T cells and thus allow for antigen-specific T cell-dependent antibody responses.

This function of the BCR is heavily dependent on the Igα/Igβ heterodimer and optimally requires the cytoplasmic domains of both these chains. Thus, the cytoplasmic domains of Igα and Igβ seem to provide complementary functions, in addition to the redundant functions of the ITAMs of these two polypeptides (Siemasko and Clark 2001). The mechanisms of these complementary functions for antigen uptake and trafficking to the correct compartment inside the B cell are not known.

FUNCTIONS OF THE BCR IN B-CELL MATURATION AND ACTIVATION

As described above, pre-BCR signaling events are required for B-cell development. In contrast, too much BCR signaling in immature B cells arrests their maturation and blocks exit from the bone marrow. These cells undergo further VJ recombination events at the light chain loci, a process called receptor editing (Nemazee 2000). If antigen specificity is changed by these rearrangements such that the B cell is no longer self-reactive, it can presumably exit the bone marrow and resume maturation. Once in the periphery, transitional B cells must choose between additional tolerance fates (clonal deletion or clonal anergy) and three possible mature cell types: B-1 cells, marginal zone B cells, and follicular recirculating B cells (also called B-2 cells). The BCR is thought to play important roles in all of these cell fate decisions (Meffre et al. 2000; Cariappa and Pillai 2002; Gold 2002; Kurosaki 2002a). How this occurs is poorly understood because it seems unlikely that simple quantitatively different thresholds for each possible fate can explain these different outcomes. In any case, once mature B cells are present, they require a low level of BCR signaling for continued survival (Lam et al. 1997). A higher level of BCR signaling leads to activation of the B cell, as is summarized briefly here.

In mature B cells that encounter antigen, BCR signaling is important for initial activation of the B cell. If the antigen is highly polymeric in nature, such as a repetitive carbohydrate epitope on a bacterial cell surface or a highly repetitive protein determinant on a virion, it will induce very strong signaling reactions and this induces a T-cell-independent mode of B-cell activation. This rapid IgM immune response is produced by marginal zone B cells and B-1 cells, and appears to serve an early defense role in response to infection (Bachmann and Kopf 1999; Martin and Kearney 2001).

Most antigens induce a lower level of BCR signaling, and B-cell activation in this case is dependent on productive interactions with antigen-specific helper T cells. BCR signaling induces follicular B cells to migrate to the outer T-cell zone of the lymph node, Peyer's patch, or splenic white cord. Some of the helper T cells activated by antigen-presenting dendritic cells also migrate to this same region, where they scan B cells for the requisite MHC class II–peptide complexes. If the helper T cell finds a B cell that presents the correct peptide–MHC complex, this leads to a stable interaction lasting many hours. Marginal zone B cells can also participate in T-cell-dependent antibody responses.

Among the signals that the activated helper T cell provides for the antigen-stimulated B cell are CD40L and cytokines such as IL-4 and IL-5. Interestingly, CD40L stimulation, in addition to being a key activation signal, also induces Fas on the B cell and makes it

susceptible to Fas-induced apoptosis. BCR signaling protects against Fas-induced death in this circumstance (Rathmell et al. 1995; Rothstein et al. 1995), and this may be one way that anergic B cells are prevented from making T-cell-dependent antibody responses, because anergic B cells signal poorly through their BCR (Cooke et al. 1994).

Another function of CD40L is to induce the B cell to initiate a germinal center reaction, where there is both class switching and somatic hypermutation followed by affinity selection. The affinity selection step is believed to require both BCR signaling function and BCR antigen uptake function. Antigen in the germinal center is held on the surface of follicular dendritic cells and B cells with high-affinity BCRs can interact with this antigen and receive a survival signal. In addition, these B cells extract the antigen from the follicular dendritic cells, take it up and present it to helper T cells, which have also migrated into the germinal center (Batista et al. 2001). These helper T cells provide an essential role in promoting activation of these germinal center B cells. Therefore, the BCR again plays a critical role in the germinal center reaction, the products of which are high-affinity isotype switched antibody produced by long-lived plasma cells and high-affinity memory B cells.

CONCLUSION

The BCR is composed of the membrane-bound form of Ig bound to a heterodimer of Igα and Igβ (CD79a and -b). Membrane Ig has the antigen-binding function of the receptor whereas the cytoplasmic tails of Igα and Igβ mediate the signaling function. Pre-B cells express a related receptor called the pre-BCR, which differs from the BCR in that it has the two surrogate light chains, Vpre-B1 and λ5, in place of the Ig light chains.

The pre-BCR and the BCR function in two ways: by generating tonic signals that induce developmental transitions and/or provide survival signals, and by generating stronger signals on antigen-induced clustering. The latter type of signaling causes developmental arrest of developing B cells in the bone marrow, tolerance-related effects such as deletion and anergy of immature B cells in the periphery, and activation of mature B cells. Little is known about the events important for tonic signaling, with the exception of pre-BCR signaling, which has been genetically studied in detail, as illustrated in Figure 3.

Antigen (or anti-Ig)-induced signaling is understood in outline and many of the signaling reactions are reasonably well defined. BCR clustering leads to movement of clustered receptors into lipid raft microdomains of the plasma membrane, where signaling molecules such as Src family tyrosine kinases are localized. This leads to phosphorylation of ITAM sequences in the Igα and Igβ cytoplasmic domains, which in turn recruits the Syk tyrosine kinase. Once activated, Syk phosphorylates downstream signaling components that mostly function by assembly into signaling complexes. Signaling events activated include PIP_3 generation, PIP_2 hydrolysis, calcium elevation, activation of small GTPases including Ras, Rac, and Rap1, and eventually activation of transcription factors that lead to alterations in gene expression. Much remains to be learned about how downstream events are mediated, particularly those related to the biological functions of the BCR.

Monoclonal antibody therapy

ANDREW J.T. GEORGE

Introduction	1	Genetic engineering	10
How antibodies kill targets	2	Conclusion	19
Problems with antibody therapy	10	References	19

INTRODUCTION

The possibility of using antibodies in the treatment of diseases was first recognized in the 1890s when it was shown that antibodies to bacterial exotoxins were responsible for immunity to tetanus and diphtheria, and that antisera to cholera vibrios could transfer immunity to naive animals (Silverstein 1988). At the start of the twentieth century, until the advent of microbial chemotherapy, antibodies played a major role in the treatment of a wide range of infectious diseases. More recently polyclonal antibodies are routinely used for tetanus, rabies, hepatitis B, and other infectious diseases (Oral and Akdis 2000), as well as for the prevention of immunization of the mother in cases of rhesus incompatibility (Moise 2002).

Therapy in most cases has been with polyclonal antibodies, produced either by immunization of animals with the appropriate antigen or by purification of human immunoglobulin (Ig). A new opportunity was offered by the invention in 1975 of the hybridoma approach to isolating monoclonal antibodies of a desired specificity (see

Antibodies and B lymphocytes) (Kohler and Milstein 1975). It is worth noting (see below) that monoclonal antibodies are not inherently better than polyclonal antibodies; indeed for many applications polyclonal antibodies are more potent. The big advantage of monoclonal antibodies is that it is possible to produce essentially unlimited amounts of antibody with a predetermined specificity.

Polyclonal antibodies versus monoclonal antibodies

It is often assumed that monoclonal antibodies are to be preferred to polyclonal antibodies for most clinical applications. However, although there are very good practical reasons to opt for monoclonal antibodies, there can be advantages to using polyclonal antibodies. Hybridoma technology is one of the possible ways of generating monoclonal antibodies; there are others, such as phage display, which are discussed below. Indeed tumors of antibody-producing cells produce monoclonal antibodies, although normally of unknown specificity. Monoclonal antibodies, as implied by their name, are derived from a single clone of B cells. As such they react with a single epitope on the target. Polyclonal antibodies, on the other hand, react with a range of epitopes. This has the advantage that it is harder for the target (e.g. an infectious pathogen or neoplastic cell) to mutate in order to escape from attack by a polyclonal antibody, because it would need to alter many epitopes. It also makes polyclonal antibodies more robust at reacting with different strains of infectious agent. The ability of polyclonal antibodies to bind to multiple epitopes makes it easier for them to precipitate out molecules from solution, because they can form a lattice with the target molecules. In general the target can also get coated with more antibody molecules (including those of different isotypes) when a polyclonal antibody is used, making recruitment of effector mechanisms more efficient.

The main advantage of monoclonal antibodies produced by hybridoma technology is that it is possible to make large quantities of the antibody. Polyclonal antibodies are derived by bleeding immunized animals and purifying the antibodies obtained from the sera. The amount of antibody that can be obtained from one animal is limited, and once it has been used up the process has to be repeated – resulting in considerable batch-to-batch variability. This also militates against a

thorough characterization of the antibody, because much of it would be used in the characterization process. In the case of a monoclonal antibody it is worth investing considerable time and effort into characterizing the antibody specificity because it is possible to generate as much antibody as is required. In addition, monoclonal antibodies are valuable when an antibody against a single antigen that is difficult to isolate in a pure enough form to immunize an animal is required. Finally, the use of monoclonal antibodies that can be produced in defined cell lines in vitro obviates many of the safety considerations inherent in using antibodies isolated from animals (including humans) that may carry infectious organisms.

When monoclonal antibodies were first described there was considerable optimism that they would form the next generation of therapeutic agent, acting as 'magic bullets' that could be used to seek out and destroy target cells. This was fuelled by early data from lymphoma, in which the first patient treated with an anti-idiotypic antibody specific for his tumor cells went into long-term complete remission (Miller et al. 1982). However, after a period in which there was considerable investment in antibody-based therapies with little return, disillusionment spread and there was a belief that those antibodies would play little role in the clinic. In recent years the picture has changed (Glennie and Johnson 2000; Carter 2001). There has been a considerable increase in the number of antibody molecules licensed by the US Food and Drug Administration (FDA) (Table 1) and the antibody field is now one of the fastest growing areas of the pharmaceutical industry.

One of the problems with our thinking about the use of antibodies is probably with the term 'magic bullet', which has been overused in many papers, grant applications, and business proposals over the years. It is a somewhat unfortunate term, even if originally coined by the father of antibody therapy, Paul Ehrlich, to describe the targeting of toxic substances with antibodies. The term 'magic bullets' suggests a guided missile, and that if such an antibody was injected into a patient it would somehow sense where its target is and home to, and kill, it. In fact, administration of antibodies to a patient results in their distribution throughout the body, and if they happen to bump into their target they will bind to it (for a while). It could be argued that this inappropriate term has befuddled our way of thinking about antibody therapy.

In this chapter, some of the reasons why it has taken 25 years for antibodies to make an impact are discussed, and some of the more futuristic applications of these molecules considered.

HOW ANTIBODIES KILL TARGETS

One of the important questions in antibody therapy is how antibodies work in therapeutic settings. In general this can be divided into three categories: those that rely on the natural functions recruited by antibodies, those that use the ability of antibodies to bind to soluble or cell surface receptors, and those that harness artificial effectors.

Recruitment of natural effectors

COMPLEMENT

The Fc region of antibody molecules is capable of recruiting the complement cascade, as described in much more detail in Complement and reviewed in Walport (2001a, b). This has several consequences, including the release of soluble mediators such as C5a, which act as proinflammatory anaphylatoxins, and the coating of the target with molecules such as C3b, which serve as opsonins, aiding recognition and phagocytosis by macrophages and other phagocytes. In addition, the deposition of the membrane attack complex (the final step of which involves polymerization of C9) can lead to osmotic lysis of the target cell.

In addition to promoting inflammation and destruction of the target cells, complement has a number of other important functions. Complement deposition can reduce the size of immune complexes that form between antibodies and antigens (Miller and Nussenzweig 1975). In addition complement is involved in the processing and clearance of immune complexes, e.g. in patients with C2 deficiency no splenic uptake of immune complexes is observed (Davies et al. 1993). More recently complement has been implicated in the clearance of apoptotic bodies (Taylor et al. 2000). Finally, complement deposition is also important in the generation of antibody responses after immunization (Pepys 1974), in part because of the presence of complement receptors on the surface of follicular dendritic cells and also because the binding of C3d by CD21 (complexed to CD19) on B cells is important in B-cell activation (Fearon and Carroll 2000).

Thus, complement activation is important not only because of its potential direct role in the destruction of the target pathogen, but also because it is involved in the clearance of the resulting debris from the body and the immunization of the individual against the pathogen.

Fc RECEPTOR-MEDIATED KILLING

A wide range of cells expresses receptors for the Fc region of the antibody molecule (FcR), and interaction of the Fc with the FcR has a range of effects (Ravetch and Bolland 2001). These can include the promotion of phagocytosis (e.g. by macrophages and other phagocytes; see Phagocytes part 1: Macrophages), the induction of antibody-directed cellular cytotoxicity (ADDC) (by natural killer (NK) cells; see Natural killer cells), the release of inflammatory mediators (e.g. following interaction through the FcεR of mast

Table 1 *Antibodies approved for clinical use* [a]

***Trade name* (Proper name)**	**Indications for use**	**Specificity**	**Nature**	**Manufacturer**	**Date approved**
Avastin (Bevacizumab)	Metastatic colorectal cancer	VEGF (vascular endothelial growth factor)	Humanized	Genentech	2004
Bexxar Tositumab and I^{131} Tositumab	$CD20^{+}$ NHL	CD20	^{131}I labeled / unlabeled murine	Corixa	2003
Campath (Alemtuzumab)	B-CLL	CD52	Humanized	ILEX	2001
CEA-scan (Arcitumomab)	Imaging colorectal carcinoma	CEA	^{99m}Tc labeled Fab′ murine	Immunomedics	1996
Erbitux (Cetuximab)	Colorectal cancer	Epidermal growth factor receptor	Chimeric	ImClone	2004
Herceptin (Trastuzumab)	Breast cancer	HER–2/*erb* B2	Humanized	Genentech	1998
Humira (Adalimumab)	Rheumatoid arthritis	TNF	Human (phage derived)	Abbott Laboratories	2002
Leukoscan (Sulesomab)	Imaging inflammation/ infection in osteomyelitis	NCA 90 (granulocyte marker)	^{99m}Tc labeled Fab murine	Immunomedics	1997 EU
Myoscint (Imciromab pentetate)	Cardiac imaging	Cardiac myosin	^{111}In labeled Fab murine	Centocor	1996
Oncoscint (Satumomab pendetide)	Imaging colorectal/ovarian carcinomas	TAG-72	^{111}In labeled murine	Cytogen	1992
Orthoclone (muromonab-CD3)	Renal allograft rejection	CD3	Murine	Ortho	1986
Panorex (Edrecolomab)	Rectal/colon cancer	17-1A	Murine	Johnson & Johnson	1995 (Germany)
Prostascint (Capromab pendetide)	Imaging prostatic cancer	Prostate-specific membrane antigen	^{111}In labeled murine IgG	Cytogen Corp	1996

Raptiva (Efalizumab)	Psoriasis	CD11a	Humanized	Genentech	2003
Remicade (Infliximab)	Rheumatoid arthritis and Crohn's disease	TNF	Chimeric	Centocor	1999
ReoPro (Abciximab)	Cardiac intervention, unstable angina	Glycoprotein IIb/IIIa (GPIIb/IIIa) receptor of human platelets	Fab fragment of chimeric antibody	Centocor	1997
Rituxan/Mabthera (Rituximab)	Non-Hodgkins lymphoma	CD20	Chimeric	Genentech/Hoffman La-Roche	1997
Simulect (Baxsiliximab)	Renal transplantation	CD25	Chimeric	Novartis	1998
Synagis (Palivizumab)	Respiratory syncytial viral infection (RSV)	F protein of RSV	Humanized	MedImmune (USA)Abbot (EU)	1998
Verluma (Nofetumomab)	Imaging small cell lung cancer	40 kDa carcinoma associated antigen	^{99m}Tc labeled Fab fragment of murine antibody	Dr Karl Thomae GmbH	1996
Xolair (Omalizumab)	Asthma	IgE	Humanized	Genentech	2003
Zenapax (Daclizumab)	Renal allograft rejection	CD25	Humanized	Hoffman La Roche	1997
Zevalin (Ibritumomab Tiuxetan)	Non Hodgkins lymphoma	CD20	^{111}In and ^{90}Y labeled murine antibody	IDEC	2002

a) The table lists the majority of current approved drugs (withdrawn drugs not given) as of 2004. The date of first approval is shown, there may have been subsequent approvals for other indications. Approval date is shown for the USA unless otherwise indicated. Data from web and personal communications.

cells and basophils; see Basophils and eosinophils), and clearance from the circulation by cells of the reticuloendothelial system (see Phagocytes part 1: Macrophages). In some cases these functions will be enhanced by complement activation. In addition the interaction of the Fc region with FcRs is important in controlling humoral immunity (Ravetch and Bolland 2001).

GENERAL CONSIDERATIONS FOR THE RECRUITMENT OF NATURAL EFFECTORS

One of the features of the use of monoclonal antibodies is that a single Ig isotype is employed. This is either of rodent origin or, after antibody engineering, may be a human isotype. It is clearly important to select an appropriate isotype for the recruitment of the appropriate effector functions. This assumes that the important effector function is known and often this can be difficult to determine, e.g. in the case of neoplastic disease there is still little consensus as to whether recruitment of complement or ADCC is important in treatment. The ability of different rodent or human Fc regions to recruit human effectors has been well described; however, the situation is not simple. There are polymorphisms in FcR that influence their ability to bind to particular subclasses of antibody; e.g. the FcγRII (CD32) receptor is polymorphic in the human population, with one form (H131) binding to IgG2 and the other (R131) not (Warmerdam et al. 1990). The allotype of the antibody can also be important in its ability to bind to FcR (Greenwood and Greenwood 1993). Other factors can also determine the ability of an antibody to recruit an effector function, such as the distance from the epitope to the cell surface, as well as the orientation and density of the epitope (Bindon et al. 1988). It is therefore important to determine for each individual antibody what effector functions it can recruit.

Blocking or activation by antibodies

Until recently the main focus has been on the use of antibodies as killing agents, using natural or artificial effector mechanisms. More recently we have come to an appreciation that they can act to modulate cellular responses, either by blocking the interaction of soluble molecules, such as cytokines, with their receptors, or by binding to molecules on the cell surface that then signal to the cell.

BLOCKING BY ANTIBODIES

Antibodies are widely used in experimental settings to block the action of cytokines or other soluble molecules. This can be done using either antibodies against the soluble molecule or a blocking antibody against the receptor.

In the clinic, the most advanced version of this application for cytokines is the administration of antibodies to tumor necrosis factor-α (TNF-α) in the treatment of rheumatoid arthritis and other inflammatory disorders (Taylor 2000). The first such trial involved a chimeric anti-TNF-α antibody (cA2, infliximab) (Elliott et al. 1993), which was followed by a number of trials (some in combination with drug therapy (Elliott et al. 1994a, b; Maini et al. 1999; reviewed in Feldmann and Maini 2001). The overall picture is that most patients (50–60 percent) respond rapidly to treatment with infliximab, with an improvement in both symptoms and clinical signs of disease. However, when treatment is stopped patients eventually relapse, necessitating prolonged or repeated therapy. A range of anti-TNF-α agents has been produced, including humanized antibodies (CDP571), phage-derived antibodies (D2E7), and fusion proteins between the Fc region of the antibody with the p75 (etanercept) or p55 (lenercept) TNF receptors (reviewed in Feldmann and Maini 2001). TNF-α blockade has also been shown to have benefit in other inflammatory diseases, including Crohn's disease (Targan et al. 1997) and Jarisch–Herxheimer reactions (Fekade et al. 1996). Similar strategies have also been used in septic shock, although with less success (McCloskey et al. 1994), whereas treatment of multiple sclerosis with TNF-α-blocking agents appears to be deleterious (Lenercept Multiple Sclerosis Study Group and the University of British Columbia MS/MRI Analysis Group 1999).

Antibodies have also been used against other cytokines, such as interleukin-2 (IL-2). The alternative approach is to target the receptor for the cytokine, such as the CD25 receptor for IL-2, which has been used to downregulate immune responses in graft rejection. An antibody against endotoxin (HA-1A, Centoxin) was developed for use in septic shock, but was withdrawn when phase III trials demonstrated an increased mortality in patients treated with the antibody (McCloskey et al. 1994). Antibodies are also routinely used to reverse drug toxicities (such as ouabain).

As well as the modulation of cytokines, antibodies can block the access of toxins (such as diphtheria and tetanus) to receptors on cells. Similar blocking can prevent molecules on the surface of viruses from engaging receptors on the surface of cells. However, in many cases the viruses 'hide' the interaction site on their protein either in a buried location or by masking it with another protein. One of the advantages of some of the antibody engineering approaches outlined below is that it may be possible to make artificial antibodies that can bind to these buried interaction sites.

Antibodies can also block interactions between cell surface receptors. Anti-CD3 was the first antibody licensed for clinical use, and is used to block T-cell responses during graft rejection. In experimental settings, nondepleting antibodies against CD4 will block

T-cell responses by interfering in the signaling events leading to T-cell activation, whereas antibodies to adhesion molecules on either endothelial cells or leukocytes will block the recruitment of inflammatory cells.

SIGNALING BY ANTIBODIES

Antibodies are also able to signal cells by cross-linking surface receptors. The importance of this in therapy was realized in patients treated with anti-idiotypic antibody for lymphoma. It was shown in a retrospective study that cells from patients who responded to treatment with antibody showed evidence of signaling (tyrosine phosphorylation) after binding of anti-idiotypic antibody to tumor cells, whereas those that showed little or no clinical benefit did not show such signaling (Vuist et al. 1994). It is also likely that the actions of rituximab (anti-CD20) in lymphoma and trastuzumab (anti-Her2/neu) in solid tumors are in large part the result of their ability to signal to the neoplastic cells (Johnson and Glennie 2001; Yarden and Sliwkowski 2001). This can lead to synergy with other forms of therapy, such as chemotherapy, because the signaling can sensitize the tumor cells to the drug (Demidem et al. 1997).

In addition to direct signaling on the target cell, it is also possible to see an effect resulting from signaling to a nontarget cell, e.g. in an animal model of lymphoma it was shown that anti-CD40 antibodies were highly effective in tumor treatment, but only in situations when the animals had a high tumor burden (French et al. 1999; Tutt et al. 2002). Dissection of the mechanisms involved demonstrated that this was because the anti-CD40 antibody was interacting with CD40 on dendritic cells, rather than the tumor cells. The dendritic cells were activated by this interaction, and then presented tumor antigens to T cells – efficiently immunizing the mice against the lymphoma. Similar strategies could be considered in other settings where immunization is needed.

It should be noted that the signaling function can be reduced by the generation of $F(ab')_2$ molecules which lack the Fc region. The reason for this is that the Fc region can help in the signaling effect by interaction with FcR^+ cells that cross-link the antibody, so increasing its potency (Lane et al. 1991).

Artificial effector functions

The concept of antibodies as delivery agents has proved highly attractive. Thus antibodies have been conjugated to a wide range of toxic agents or other molecules in order to target the molecule to where it is needed. Some of the most common of these are discussed below. The main drawbacks with this approach are that antibody targeting, although capable of high specificity, is relatively poor at delivering large numbers of antibody molecules to the target site. In clinical trials in neoplastic disease, typically 0.01 percent of the injected dose localizes per gram of tissue (Esteban et al. 1987). This is one of those times when the concept of the antibody as a magic bullet is perhaps misleading because it suggests that a large proportion of the antibody molecules administered will reach the target site. Thus, the molecule being targeted needs to be capable of being effective in low amounts. The other side of this equation is that most of the antibody never reaches the target site. Thus, if the antibody is conjugated to a toxic molecule there is the possibility of nonspecific damage to healthy tissues.

TOXINS AND DRUGS

Toxins are one of the most obvious types of molecule to target with antibodies (Figure 1). There is a vast range of such toxins, derived from plants (e.g. ricin, saporin, gelonin), from bacteria (e.g. diphtheria and pseudomonas exotoxins), and from fungi (e.g. α-sarcin) (Thrush et al. 1996; Kreitman 1999). These molecules typically enzymatically inactivate protein synthesis, and so are highly potent, with one molecule of the toxin being capable of killing a cell. These toxins have been conjugated to antibodies, to form immunotoxins, using either chemical or genetic means.

The major problem faced with the use of immunotoxins is that it is not sufficient simply to deliver the toxin to the surface of the cell; it must enter the cytosol to be effective. Natural toxins have a range of mechanisms by which they do this, e.g. ricin, which is probably the most commonly used plant-derived toxin, is made of two chains joined by a disulfide bond (Olsnes and Kozlov 2001). The A chain is the enzymatically active chain. The B chain binds to the cell surface and facilitates entry of the A chain into the cytosol. If immunotoxins are made that consist of an intact A and B chain, they are effective, but also show considerable nontargeted toxicity because the B chain binds to all cells. However, if the B chain is removed, the toxin no longer binds to irrelevant cells, but the immunotoxin is relatively poor at entering the target cells. Several strategies have been used to block or modify the cell-binding chain, while leaving the internalization functions of the B chain intact (Thrush et al. 1996). Similar approaches have also been used with the bacterially derived toxins, although the binding, internalization, and enzymatic regions are normally found on the same polypeptide chain.

The importance of cytosolic entry also means that some antigens are better for immunotoxin delivery than others. These antigens generally internalize after binding of antibodies into endosomes. After acidification of the endosomes, toxins can escape into the cytosol. However, this remains an inefficient process, e.g. in in vitro experiments carried out using bispecific antibodies to target a toxin, saporin to lymphoma cells, it was shown that

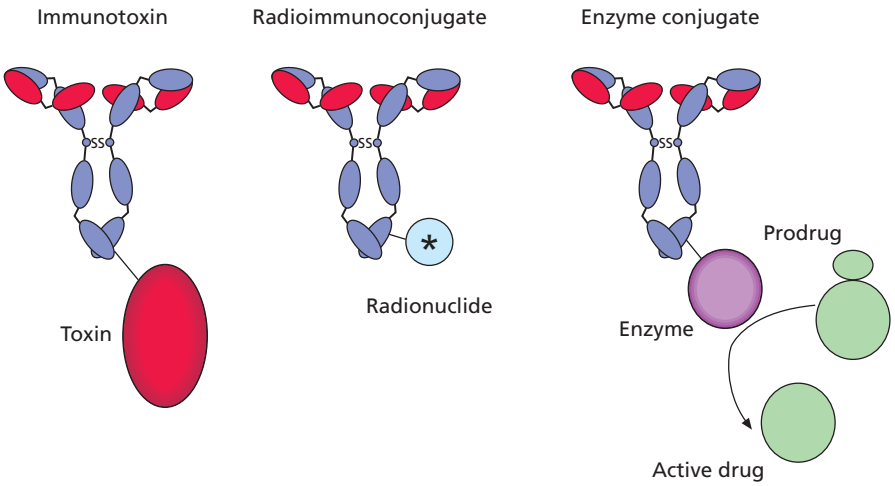

Figure 1 *Immunoconjugates: in the text three basic types of immunoconjugate are described. The first is the immunotoxin, in which the antibody is conjugated to a toxin molecule. This can lead to selective delivery of the toxin to the target cell. The second are radioimmunoconjugates, in which a radioisotope (suitable for therapy or imaging) is used. Although the targeting of the conjugate to the target is specific, the effect of the radiation will spread from that site, depending on the pathlength. Finally antibody–enzyme conjugates can be used to convert harmless prodrugs into active drugs at the target site. This leads to amplification of the targeting effect, with many copies of the drug created by each enzyme.*

constructs directed against CD22 were highly effective at killing, whereas those against CD19, CD37, and surface Ig less so. For 50 percent killing of the tumor cells it was necessary to target around 1 000 toxin molecules per cell using CD22. With the other targets, far more toxin was needed – more than 90 000 molecules in the case of CD37 (Bonardi et al. 1993). Therefore, claims about the potency of the toxins used in immunotoxins need to be treated with caution; they are incredibly toxic but only once they are in the cytosol of the cell.

The second problem about many of these toxins is that they are very immunogenic (see below for why immunogenicity is a problem). Indeed in laboratories making ricin, hypersensitivity reactions to the toxin are more problematic than the toxicity. This limits the number of times an immunotoxin can be administered. For this reason there is increasing interest in mammalian DNase and RNase molecules which have low immunogenicity (Newton and Rybak 2001). These work by degrading all the DNA or RNA in the cell, and again are highly potent if they can enter the cell.

A final problem with immunotoxins is that many of them have side effects, e.g. a limiting feature of treatment with ricin A chain is vascular leak syndrome, caused by interactions of the toxin with endothelial cells (Schindler et al. 2001). Elegant mutational analysis has allowed identification of the regions involved in this, and it may prove possible to mutate out this feature of the molecules.

In a similar manner to toxins, a number of research groups have targeted drugs using antibodies. However, a drawback of this approach is that normally a relatively large number of drug molecules is needed to see an effect. In some cases it may be possible to target enough of the drug to improve the therapeutic window of efficacy.

RADIOIMMUNOCONJUGATES

Conjugation of radionuclides to antibodies can be used for two purposes: therapy and imaging (see Figure 1). In the case of therapy a radionuclide with a short pathlength (e.g. β emitters) is used so that the damage is limited to the targeted area. For imaging, radionuclides with long pathlengths are used (γ emitters), which can be detected by an appropriate camera.

One feature of radioimmunoconjugates is that, even if the antibody is targeted specifically to a cell bearing the appropriate antigen, the killing mechanism spreads from that targeted cell. This can lead to unwanted toxicity to normal tissues. However, it can be an advantage because the radiation may kill cells that need to be killed, but are not targeted by the antibody. This might include the blood vessels feeding a tumor or tumor cells that the antibody cannot reach.

Imaging with antibodies may prove useful in a number of settings. It may localize where disease activity is, monitor its response to therapy, or even assess the nature of the disease, using specific antibodies. In most cases the antibodies used are directed against tumor cells. One exciting alternative is to image E-selectin expression on endothelial cells. E-selectin is an adhesion molecule that is expressed only on activated endothelium, seen at sites of inflammation. Not only is it a highly specific marker of inflammation, but, being expressed on the luminal surface of endothelium, it is highly accessible to antibodies in the vasculature. Antibodies to E-selectin have been used to image rheumatoid

arthritis and inflammatory bowel disease, as well as to locate occult infection in patients with acquired immunodeficiency syndrome (AIDS) (Chapman et al. 1996).

Most imaging is done with γ-emitting antibodies, which can be detected with a gamma camera, using standard nuclear medicine facilities such as single photon emission computed tomography (SPECT). However, there are alternatives, including the delivery of positron emitters for positron emission tomography (PET) and magnetic contrast agents for magnetic resonance imaging (MRI) (Weissleder and Mahmood 2001). Antibodies have even been conjugated onto bubbles, with a view of developing targetable contrast agents for ultrasonography (Villanueva et al. 1998). Each imaging modality has particular advantages, giving complementary information for clinical diagnosis. The ability to use antibodies to localize the expression of molecules on cells has enormous potential not only for clinical diagnosis but also for the careful monitoring of novel therapies.

ENZYME CONJUGATES

One of the most promising, although also complex, forms of immunotherapy relies on targeting an enzyme within a tumor, often termed 'ADEPT'. Once the enzyme–antibody conjugate has been allowed to localize to the target site, an inactive prodrug is given that is converted by the enzyme into its active form (see Figure 1). There are several such enzyme–prodrug combinations that have been developed (Niculescu-Duvaz et al. 1999; Syrigos and Epenetos 1999). In many cases the prodrug is a modified version of a standard drug already in use.

There are several advantages to this approach. The first is that both agents administered to the patient (antibody–enzyme conjugate and prodrug) are essentially nontoxic, and only become toxic when combined. If a drug is chosen that has a short half-life, the toxicity is limited to close to the site of activation. The second is that targeting a single enzyme molecule can facilitate the production of thousands of drug molecules; there is therefore an inbuilt amplification step. In addition in most cases (in neoplastic disease) the drug is more cytopathic to tumor cells than normal cells, so reducing the toxicity to normal tissue around the activation site. At the very least, this approach should improve the therapeutic window of drugs.

The drawback to this approach is the complexity. Not only are there two agents that need to be optimized, but also the timing of the administration of the antibody–enzyme conjugate and the prodrug needs to be optimized. The prodrug cannot be administered while there is free antibody–enzyme in circulation, otherwise drug activation will not be localized to the tumor. To avoid waiting a long time for unbound conjugate to clear, most groups are devising methods to clear the antibody–enzyme from the circulation. Administering a second antibody (e.g. anti-enzyme, anti-idiotypic, or anti-mouse) that binds to the conjugate and causes clearance can do this. Alternatively, the glycosylation status of the antibody can be used to ensure rapid hepatic clearance.

Thus, although attractive, ADEPT has still to make a major impact in the clinic. It is perhaps surprising that all the attention has focused on neoplastic disease for this approach to therapy. It might be thought that this would be useful for focusing the action of anti-parasitic or anti-inflammatory drugs to sites where they are needed.

BISPECIFIC ANTIBODIES

Natural antibodies are monospecific, i.e. they have a single form of the antigen-binding site. Bispecific antibodies are an artificial form of the antibody that has two distinct antigen-binding sites (Figure 2).

There are three ways to prepare bispecific antibodies: chemical, hybrid hybridoma, and recombinant. Chemical methods (reviewed in Segal et al. 1992) range from relatively crude crosslinking with molecules, such as *N*-succinimidyl-3-(2-pyridyldithio) propionate (SPDP), which yield a heterogeneous product, to highly precise production of clinical grade material, e.g. by conjugation through the hinge-region cysteines of Fab′ molecules (Glennie et al. 1987). Hybrid hydridoma technology relies on the fusion of two monoclonal antibody-producing hybridomas (Milstein and Cuello 1983). The advantage over the chemical approach is that the result is a cell line that secretes the bispecific antibody on a permanent basis. However, because of random assortment of the two heavy and two light chain domains, a large number of antibody species is produced – only one of which is bispecific. It is necessary to find ways of purifying the desired molecule from the others. The final way to generate bispecific antibodies is by recombinant DNA technology (George and Huston 1997); a number of constructs have been made, mostly based on the basic scFv unit (as discussed below). The final choice as to which method is used will depend on the amount of material needed, the grade it has to be made to, and also whether it is important that the molecule is monovalent or polyvalent to the antigens (i.e. the number of antigen-binding sites present).

Bispecific antibodies can be specific for soluble molecules (Figure 2). In this way they are essentially acting as immunoconjugates, and toxins, drugs, and radionuclides have also been targeted in this way (French et al. 1995). It is not necessary to make a conjugate between the antibody and the other effector molecule, which can damage the effector. It would theoretically be possible to administer the bispecific antibody and the effector molecule separately, which, if the effector has a short half-life, should reduce toxicity.

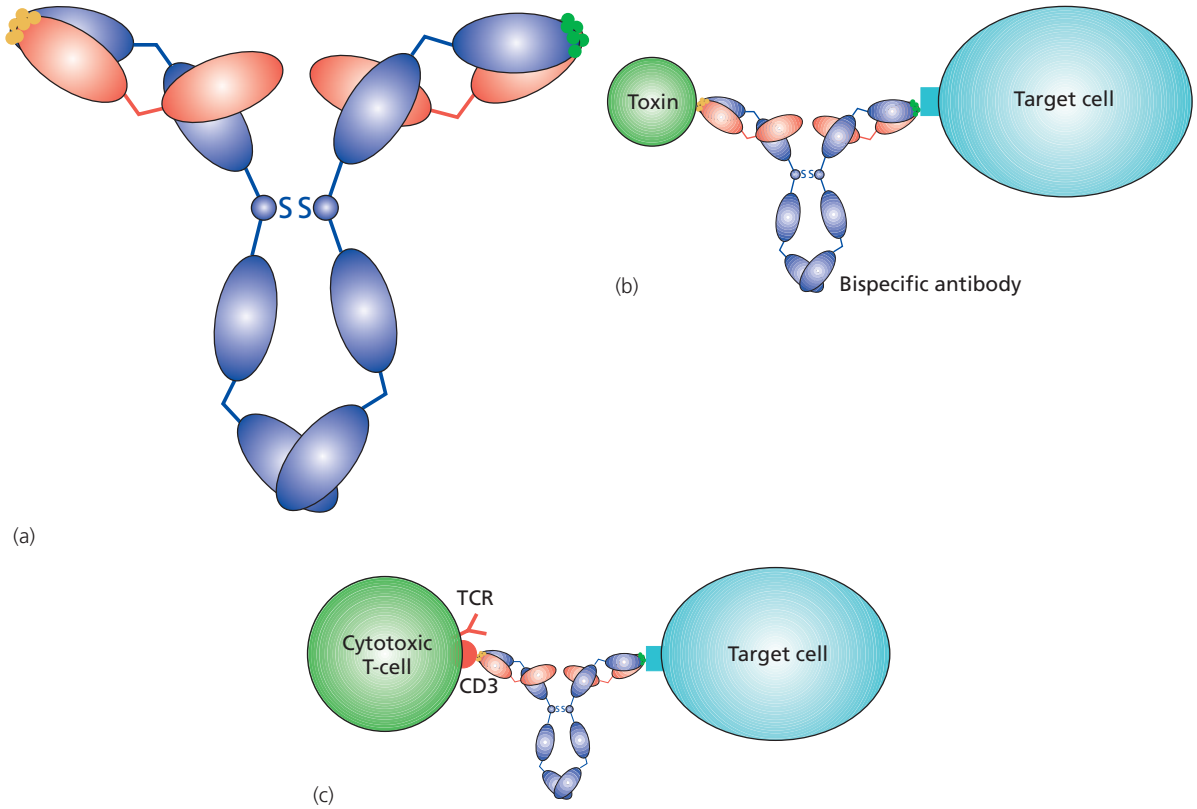

Figure 2 *Bispecific antibodies have two distinct antigen-binding sites, as illustrated here* **(a)** *using different colours for the CDR regions. They can be used to target soluble molecules or effector cells to the target site as shown for* **(b)** *targeting toxins and* **(c)** *cellular cytotoxicity.*

However, the pharmacokinetics of antibody delivery would mean that this is an inefficient process. This process is also highly dependent on the affinity and kinetics of the bispecific antibody to both the target cell and the therapeutic molecule (George et al. 1995a).

In addition to targeting effector molecules, bispecific antibodies can also be used to target immunogens to antigen-presenting cells, to boost immune responses (Snider and Segal 1989), e.g. bispecific antibodies specific for hen egg lysozyme and major histocompatibility (MHC) class II molecules on antigen-presenting cells (as well as some other molecules) have been shown to be effective in vivo at immunizing animals (Snider et al. 1990).

The above applications for bispecific antibodies are essentially similar to those for immunoconjugates. However, one way in which bispecific antibodies can be used is to target cells (Karpovsky et al. 1984; Perez et al. 1985) (Figure 2). In this case the bispecific antibody has to be specific for a molecule on the effector and the target cells. The effector cell could include T cells, neutrophils, NK cells, or any other cell capable of mediating an appropriate response. The bispecific antibody serves not only to bring the two cells together, but also to trigger the effector cell. For that reason the antibody must interact with a 'trigger molecule' on the effector cell, such as CD3 on T cells or FcγRIII (CD16) on NK cells.

The main application of this approach is to kill neoplastic or virally infected cells. The advantage of this strategy is that the effector cells are appropriate for the targets (e.g. the main function of CD8 cells is to kill virally infected cells). They are therefore efficient at the task.

Bispecific antibodies can also be used to activate cells, e.g. combinations of bispecific antibodies can be used that engage not only the trigger molecule on the effector cells, but a co-stimulatory molecule to activate the cell (such as CD28) (Grosse-Hovest et al. 1999). It is even possible to generate trispecific antibodies that engage two molecules on the effector cell, a triggering molecule and an activating molecule (Tutt et al. 1991).

There have been a number of clinical trials using bispecific antibodies (Segal et al. 1999; van Spriel et al. 2000). Some of these have shown promising results; however, progress is slow. The reasons for this are likely to lie in the complex nature of the therapy being attempted; it is necessary to ensure that the antibody and the effector cells both reach the target tissue and that the effector cells are adequately activated. However, the ability to target effector cells that are

optimal for the killing of the target cell remains highly attractive.

OTHER CONJUGATES

Although the above strategies represent the main ones being developed or used for therapy, the ability to conjugate antibodies using chemical or molecular techniques can be applied to an enormous range of partners, e.g. antibodies linked to magnetic beads can be used to purge bone marrow of malignant cells (Gee et al. 1992). Antibodies have also been used to target cytokines such as IL-2 to stimulate immune cells at specific sites (Boleti et al. 1995). In addition antibodies can also be used to target gene therapy vectors, both viral (Harari et al. 1999) and nonviral (Tan et al. 2003), to specific cells.

PROBLEMS WITH ANTIBODY THERAPY

Given the plethora of different strategies described above, it has to be asked why antibody therapy is not more successful. Some of the major problems with antibody therapy are given here and, in the next section, the genetic strategies that can be used to overcome these are considered.

Immunogenicity

Nearly all monoclonal antibodies produced by hybridoma technology are of mouse or rat origin. This means that when they are introduced into patients they are immunogenic. They therefore elicit an immune response, which can be seen as a human anti-mouse (or rat) antibody (HAMA) response. The production of HAMA has two consequences. First, the antibodies bind to the therapeutic antibody, making it ineffective by blocking it and removing it from circulation. Second, the formation of immune complexes with the antibody can lead to serum sickness (type III hypersensitivity). Similar responses against the effector molecule in immunoconjugates (such as toxin molecules) can have a similar effect. The result of this is that it is frequently impossible to give repeated administrations of antibodies to patients.

Pharmacokinetics

Antibodies are large molecules compared with most drugs (around 150 kDa). This means that they are relatively poor at penetrating solid tissue, especially in cases where the tissue has a high interstitial pressure (such as tumors). This limits their ability to get to where they are needed. In addition the large size of antibodies (as well as their interaction with the Brambell receptor FcRn – Junghans 1997) means that they have a long half-life ($t_{1/2}$). The $t_{1/2}$ of a human IgG1 antibody in a patient is around 21 days. Although most murine antibodies have a shorter half-life in patients, this means that large amounts of unbound antibody remain in the circulation for significant periods after administration. If the antibody is conjugated to a cytotoxic agent, this increases the nonspecific toxicity. In addition, for other applications, such as imaging, the unbound antibody provides a background that needs to clear in order for the specific bound antibody to be detected.

Loss of antigen

If the target loses the antigen recognized by the antibody, it can escape attack. This can occur (for both pathogens and neoplastic cells) by mutation of the antigen. In some parasites there are well-described strategies for switching surface antigens to enable them to escape antibody attack. In addition, the loss of antigen can be temporary, caused by modulation of surface antigen (patching, capping, and internalization or shedding of antigen complexed with antibody).

Nature of antigen

Some of the antigens chosen for antibody therapy are not effective because they are not expressed on all the cells (perhaps because of differential expression through the cell cycle). In addition, as discussed above for the immunotoxins (see section on Toxins and drugs), some antigens are better at delivering effector molecules to the cell than others. Expression of the same (or cross-reactive) epitopes on other cells can also cause problems, e.g. ricin A chain containing-immunotoxin was infused into five patients with breast cancer, most of whom developed marked fluid overload and debilitating sensorimotor neuropathies. This was probably the result of an unexpected recognition by the antibody of a molecule on Schwann cells, which resulted in demyelination of the patients' neurons (Gould et al. 1989).

GENETIC ENGINEERING

Many of the problems outlined above have been tackled using the tools of antibody genetic engineering. There are three aspects of antibody production that genetic engineering has influenced: the selection of novel antibodies, the design and construction of 'improved' antibody molecules, and the inexpensive production of antibodies using mammalian, eukarytotic, and prokaryotic cells (outside the scope of this chapter, but reviewed in Verma et al. 1998).

Production of new antibodies

Hybridoma technology has proved a powerful tool for generating monoclonal antibodies. However, it has some severe limitations. The first of these is that it is limited to the production of mouse, rat, or hamster antibodies. Although some groups have been able to use hybridoma

technology to make antibodies from other species (including humans), for a variety of technical reasons (difficulty of immunizing, problems with fusion partners) this has never been routine.

The second problem relates to the way in which hybridoma technology is used to screen for antibodies. This relies on screening individual wells containing hybridomas to see whether they contain an antibody of the desired specificity. This process is inherently inefficient, and so it is difficult to obtain antibodies that are rare. To give a practical illustration of this, if we want to isolate a hybridoma that is present at a frequency of 1/10 000 one would need to screen in the order of 100 96-well plates in order to find it, and that is assuming that every well contains one hybridoma.

This has led to a number of approaches for generating novel antibodies, such as phage display (McCafferty et al. 1990; Clackson et al. 1991) and ribosome display (Hanes and Pluckthun 1997; He and Taussig 1997). Of these, phage display is the most commonly used. In addition, transgenic mouse technology has allowed the production of human antibodies using conventional hybridoma technology (Bruggemann et al. 1991).

PHAGE DISPLAY

Filamentous bacteriophages (such as M13) are single-stranded DNA viruses that infect bacteria such as *E. coli*. They are long phages, typically 1 μm, and around 6–7 nm in diameter. The single-stranded DNA is covered with coat proteins, in particular the major coat protein pVIII, which is present at around 2 700 copies per phage, and a number of minor coat proteins of which the most important for our purposes is pIII, which is present at around three to five copies at one end of the phage.

To carry out phage display it is necessary to make recombinant antibody fragments (see section on Antibody fragments) fused to one of the coat proteins of the phage (for a review of this technology, see Winter et al. 1994; George and Epenetos 1996). Several fragments have been fused to a number of coat proteins, but, for simplicity, scFv fragments fused to pIII are considered here. This is probably the most commonly used format, although many groups use Fab fragments.

In the basic protocol (Figure 3), B cells are used as a source of mRNA. This is reverse transcribed to cDNA and polymerase chain reaction (PCR) used to isolate the gene fragments encoding the heavy and light chain variable domains. These are cloned into the phage as scFv (or Fab) fragments fused to the gene encoding pIII. When these phages are expressed in bacteria they are generated as phage particles that express antibody fragments on their surface (McCafferty et al. 1990). The result of this is a library of phages expressing a large number of antibody molecules. It is now possible to take this library and incubate it with immobilized antigen (e.g. coated onto plastic). Phages expressing the antibody of interest will bind to the antigen; the rest will be washed away. Repeating this panning procedure allows the isolation of phages bearing the appropriate antibody (and also containing the gene encoding for that antibody) (Clackson et al. 1991).

Looking at the steps in the process in some more detail, the source of variable region gene can be B cells from any species from which it is possible to amplify the genes – including humans. In addition, the animal can be either immunized or 'naïve' to the antigen in question. In many cases the source of the genes is synthetic, using artificial sequences. Indeed some groups have moved beyond the antibody, and are making antigen-binding molecules based on different scaffolds, such as fibronectin-derived domains (Koide et al. 1998). This opens up the possibility of making antigen binders with a different number of complementarity-determining regions (CDR) regions, or with different sized CDR regions (long protuberant CDR may be useful to bind to buried epitopes on viruses as discussed earlier).

The size of the library is a very important factor in the process. Typical libraries will have 10^7–10^9 different antibody molecules. It is also possible to use genetic tricks to make libraries that have close to 10^{11} different antibody molecules (Griffiths et al. 1994). To put that in context, the number of different B cells in a mouse is probably around 10^8. Given that a mouse is capable of making an antibody against just about any foreign antigen, this means that it is highly likely that a library will contain an antibody of the desired specificity. The other advantage of large libraries is that the antibodies isolated are of higher affinity than those isolated from smaller libraries (Griffiths et al. 1994).

The affinity selection can take place in a number of ways. In general, purified antigen is coated on to plastic plates. Alternatively, selection can be done in solution, using biotinylated antigen followed by the addition of streptavidin-coated beads to pull the antigen–phage complex out of solution. However, selection can be done on the surface of cells (Palmer et al. 1997), on crude extracts, tissue sections (Owens et al. 2000), and even in vivo, after injection of the library into an animal (Johns et al. 2000). This latter approach allows the isolation of antibodies reactive with tissue-specific markers on endothelium. Selection can also involve negative selection steps, to remove unwanted specificities, or sequential selection on different antigens (e.g. different strains of human immunodeficiency virus (HIV) to deliberately select for antibodies capable of cross-reacting with both antigens or the use of blocking antibodies to direct the antibodies away from a particular epitope (Ditzel et al. 1995).

Once the antibody has been selected it can be modified to give it appropriate effector functions (see 'Effector functions'). However, in many cases, especially

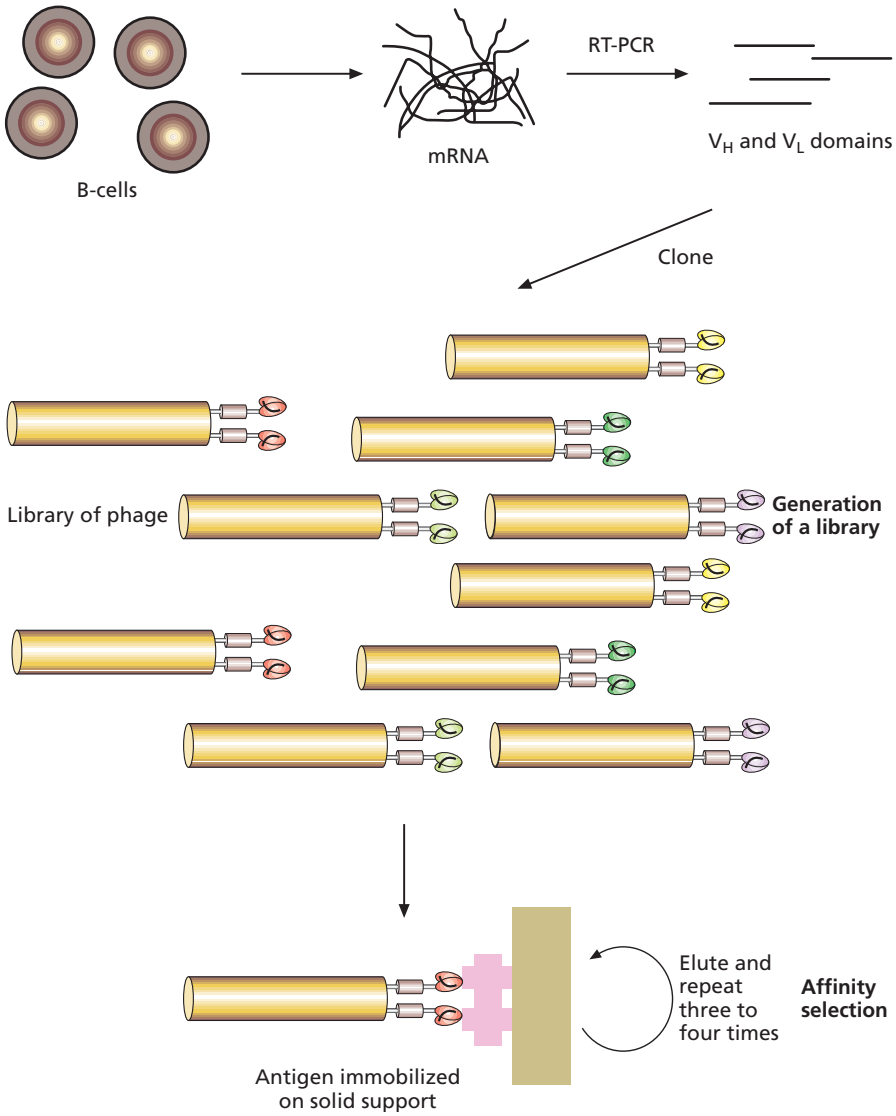

Figure 3 *In phage display technology V region genes are isolated from B cells (or artificially made) and are constructed to form a library of antibody fragments (illustrated here as scFv), displayed on the surface of filamentous phage as a fusion with a coat protein (in this case pIII). The library consists of a large number of phages, each with different antibodies on their surface, and carrying in the genome of the phage particle, the gene encoding that antibody. As a result, if affinity selection techniques are used, it is possible to isolate phage-expressing antibodies that bind to the antigen in question. This allows isolation of the gene for that antibody. The selection process has to be repeated a number of times, resulting in the isolation of an antibody specific for the antigen. RT-PCR, reverse transcriptase polymerase chain reaction.*

from small libraries, the affinity of the antibody is too low for practical use. It is possible to improve the affinity by random mutation of the antibody (using error-prone PCR or passing the phage through a mutator strain of bacteria), followed by further selection on antigen (Marks et al. 1992b). In addition, shuffling the heavy and light chains with novel heavy and light chains, and repeating the selection, can also improve affinity (Marks et al. 1992a). This process can be highly effective; in one case the affinity of anti-HIV antibodies was improved using a variety of mutational approaches from the already high affinity of 6.3 nmol/l to 15 pmol/l (Yang et al. 1995).

The process described above is highly reminiscent of the natural life history of B cells and antibody production. In the bone marrow a large library of naïve B cells is produced with different antibodies on their surface. Antigens are used to affinity select those B cells with the appropriate specificity. These are then randomly mutated and subject to further selection to affinity mature the response. The shuffling of heavy and light chains is even similar to the process of receptor editing, which may play a role in the improvement of antibody affinity (George and Gray 1999).

What are the advantages of phage display? The ability to use human or even artificial antibodies is important.

The process is also better at the isolation of rare antibodies. As antibodies are selected using an affinity technique, so long as the selection system is robust, it is possible to isolate very rare antibodies quickly. In addition, the library has never undergone negative selection or tolerance in vivo. It is therefore possible to isolate antibodies against antigens to which the animals are tolerant (Griffiths et al. 1993). In some cases this has made it possible to produce antibodies that recognize the same antigen in a variety of species (Palmer et al. 1999).

TRANSGENIC ANIMALS

One method for producing human antibodies using hybridoma technology has been to make animals in which their native Ig loci have been replaced using knockout and transgenic approaches with the human counterparts (Lonberg et al. 1994; Bruggemann and Neuberger 1996; Mendez et al. 1997; Nicholson et al. 1999; Tomizuka et al. 2000). These animals, when immunized, produce human antibodies. The antibodies undergo somatic mutation and, if the genes for the appropriate heavy chain isotype are present, can class switch. It is therefore simple to use such immunized animals to generate human monoclonal antibodies using conventional hybridoma technology.

If such transgenic approaches could be applied to larger animals, such as pigs, sheep, or cattle, it might be possible to use them as a source of therapeutic polyclonal human antibodies. It would be conceivable to immunize such animals with virus or toxoids, and to harvest the antibody from them. This should have the advantage of reducing the risks of using material derived from humans, as well as allowing the production of large quantities of defined material.

Immunogenicity

Among the first constructs to be made were those aimed at tackling the immunogenicity of rodent (mostly murine) antibody molecules. The most commonly used methods for doing this are chimerization and humanization, although other procedures such as veneering have been described. There are additional strategies for reducing the immunogenicity, including the production of nonbinding antibody molecules and removal of T-cell epitopes (termed 'deimmunization').

CHIMERIZATION

The structure of the antibody molecule is made up of domains, which essentially fold as independent units. It is therefore relatively easy to swap domains from one antibody to another. Chimeric antibodies are created by replacing all the rodent constant region domains with those of humans, resulting in a molecule where 8 of 12 of the domains are human (Figure 4) (Boulianne et al. 1984; Morrison et al. 1984). These antibodies have considerably reduced immunogenicity in patients when compared with their murine counterpart. In addition, the antibodies have human Fc regions (which can be chosen at will), and so will in general be better at interacting with human effector mechanisms than murine Fc regions.

HUMANIZATION

Although the majority of a chimeric antibody is human in sequence, the variable domains remain rodent in origin. However, most of the variable domains serve no antigen-binding function, but act as a platform for the six CDRs (or hypervariable loops) to form the antigen-binding site. This has led to the process of humanization, in which just the hypervariable loops from the rodent antibody are transferred onto human variable domains (Jones et al. 1986; Reichmann et al. 1988). The result is an antibody that is essentially totally human.

The process of humanization relies first on the identification of human variable domains that are similar in structure to the original rodent variable domains. The CDRs can then be transferred using standard recombinant approaches. When this is done, it is often found that the antibodies have a lower affinity than the parental antibody. Judicious mutation of some of the framework residues that interact with the CDRs will normally restore the affinity. Although this process was originally somewhat hit and miss, there is now a considerable body of experience that ensures that humanization is a robust and relatively routine procedure (Emery and Harris 1995).

Although humanization might seem optimal, it is important to note that the resulting antibodies are still immunogenic (Clark 2000). This is because the antigen-binding site is immunogenic and capable of eliciting an anti-idiotypic response. This is not unique, of course, to humanized antibodies; natural human antibodies are equally capable of inducing anti-idiotypic antibodies. There is no evidence that the CDRs of humanized antibodies are any more (or less) immunogenic than the CDRs of human antibodies. It is also important to realize that, although there might be theoretical advantages of humanization over chimerization, there is little evidence that the humanized antibodies are better than chimeric antibodies (Clark 2000). The immunogenicity of the six CDR loops is probably considerably greater than that of the relatively few framework residues that differ between rodent and human.

VENEERING AND DEIMMUNIZATION

Veneering antibodies relies on the realization that, if the surface of a murine antibody variable domain is compared with its human equivalent (and ignoring the

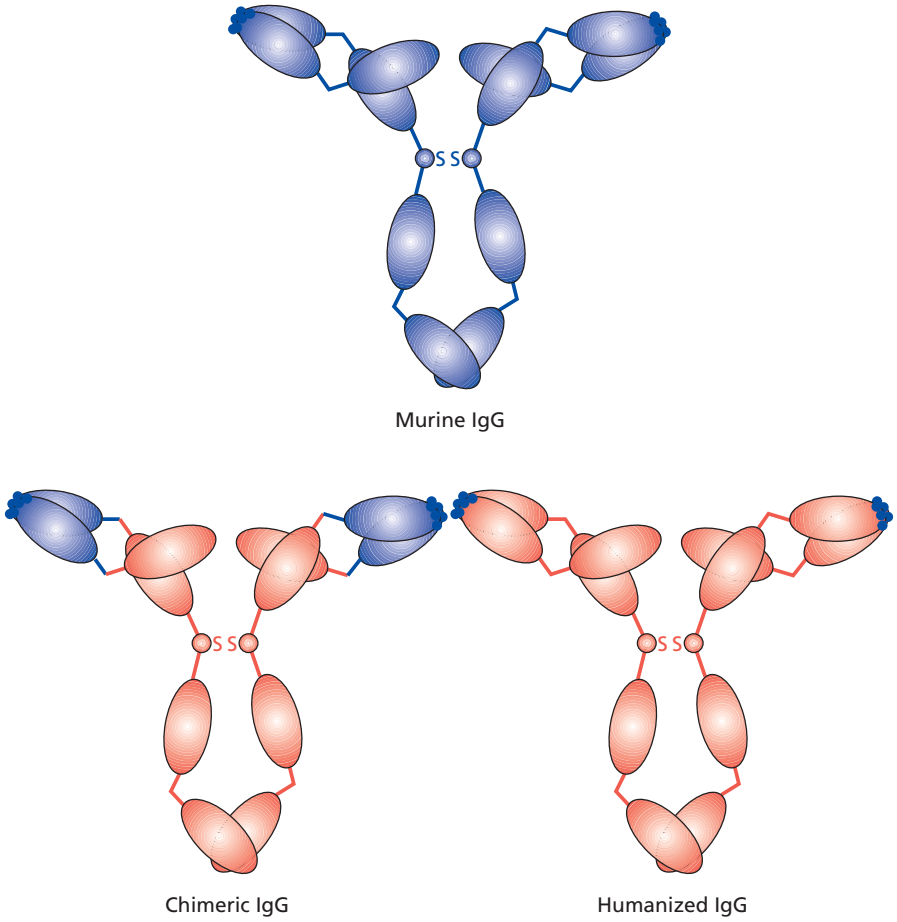

Figure 4 *Reducing immunogenicity: most monoclonal antibodies are totally rodent in origin (shown as blue). However, it is possible to replace parts of the molecule with human sequences (red). In the simplest form chimeric antibodies contain the rodent variable domains and human constant domains. In humanized antibodies all the domains are human in sequence, but the complementarity-determining regions (CDR), shown as circles, are replaced by those from the parental antibody.*

CDR regions), relatively few residues are different (Padlan 1991). Given that HAMA will recognize the surface of these domains, mutation of these few residues from the mouse to the human sequence should abolish the ability of HAMA to bind to the antibodies (Roguska et al. 1994). This approach has been termed 'veneering', because it is similar to the practice in furniture making of covering cheap wood with a veneer of expensive wood. The mouse variable domain is covered with a veneer of human amino acids.

The complementary approach to this has been termed 'deimmunization', in which it has been reasoned that to generate a HAMA response it is necessary for the relevant B cells to obtain T-cell help. As the T-helper cells will see peptide bound in the groove of MHC II molecules, and as this binding is dependent on motifs of amino acids, it should be possible to mutate out these MHC-binding motifs, making an antibody that it invisible to T cells.

Both of these approaches are elegant. However, given the success of humanization and chimerization, it is likely that they will not have a major impact except, possibly, as a way to overcome restrictive patents on the other strategies. It is possible that deimmunization may be effective in preventing anti-idiotypic responses (which require T-cell help), in which case there would be a clear advantage for this approach. However, this has yet to be shown.

TOLERANCE INDUCTION

All of the approaches outlined above are designed to make the antibody invisible to the immune system. An alternative would be to tolerize the patient to the antibody being given. One approach to this is based on the observation that the administration of soluble antibodies to patients (or animals) is normally tolerogenic. However, administration of antibodies that bind to cell surfaces is immunogenic. It is possible to produce antibodies that have mutations in their CDR loops and so no longer bind to their antigen. Intravenous injection of these antibodies (at least in animal models) tolerizes the animal to the antibody, allowing subsequent administration of the complete antigen-binding antibody with no induction of HAMA (Gilliland et al. 1999).

Antibody fragments

As noted above the large size of antibody molecules ensures that they have a long half-life and are relatively poor at penetrating solid tissue. For many circumstances this is an advantage, e.g. if the object is to maintain high levels of a blocking antibody for prolonged periods. However, in many cases it would be preferable to have antibodies that are cleared rapidly. The main approach to doing this has been to make recombinant antibody fragments, which are smaller than the native molecule.

It is fairly easy to make the range of antibody fragments (Fab, Fab′, F(ab′)$_2$ – Figure 5) that are available using conventional enzymatic digestion of antibodies. It is also possible to make novel molecules, normally based on the Fv fragment of an antibody that consists of the two variable domains of an antibody. This is the smallest antibody fragment that retains an intact antigen-binding site (25 kDa, as compared with 150 kDa for IgG). It is possible to make Fv fragments by enzymatic digestion of some antibodies (Inbar et al. 1972); however, the molecules are normally unstable because the two domains are free to dissociate (in an Fab fragment the heavy and light chains are held together by a disulfide bonds as well as noncovalent interactions that are predominantly between the two constant domains). There has been interest, therefore, in strategies to make artificial Fv-based molecules.

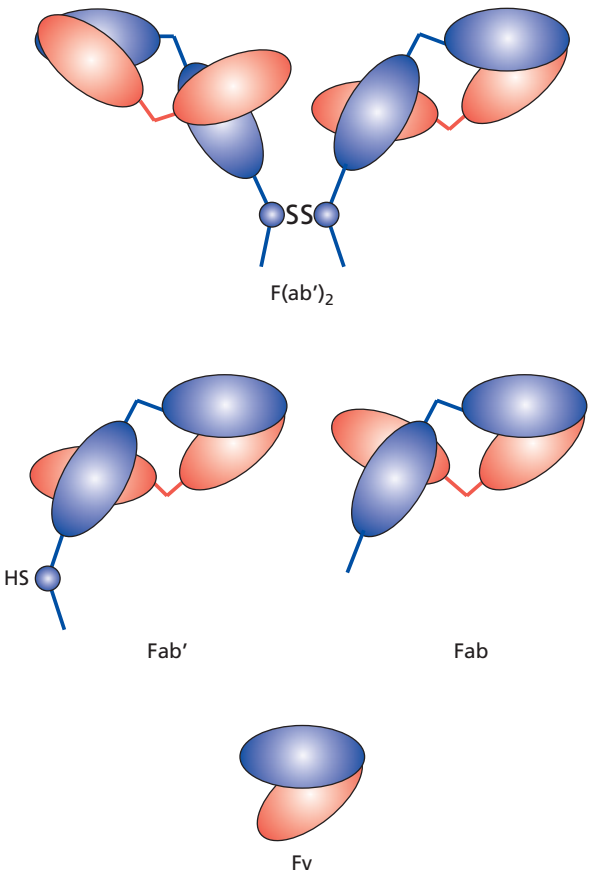

Figure 5 *Antibody fragments: the whole immunoglobulin IgG molecule can be enzymatically digested to produce F(ab′)$_2$, Fab′, Fab, and Fv fragments of the molecule, which contain intact antigen-binding sites but are smaller than the parental molecule. These are also accessible using recombinant approaches. However, the Fv in particular is unstable, because there are no disulfide bonds and only weak noncovalent interactions to prevent the two chains from dissociating.*

Fv-BASED CONSTRUCTS

The aim of all Fv-based constructs is to stabilize the interactions between the two variable domains without destroying the antibody-binding site. The first type of molecule in which this was achieved was the single chain Fv (scFv or sFv, commonly referred to as a single chain antibody). In this molecule a peptide linker is used to join the C terminus of one domain with the N terminus of the other (Bird et al. 1988; Huston et al. 1988) (Figure 6). The (linear) distance that needs to be spanned is around 3–4 nm (Huston et al. 1996a), and to do this the linker is typically around 15 amino acids; it has been designed or selected to be highly flexible (the archetypal sequence being $(Gly_4Ser)_3$, with the glycines providing maximal flexibility – Huston et al. 1988). However, many other linker sequences have been designed or selected by phage display (Turner et al. 1997). The format of the scFv can be V_H–linker–V_L, or V_L–linker–V_H, whereas some scFvs perform better in one orientation than the other; in most cases the choice is unimportant.

The scFv has the advantage of being a robust building block for the generation of targeting molecules, in large part because of its simplicity; it is a single polypeptide chain encoded by a single gene construct. The pharmacokinetics of the scFv are as might be expected from its small

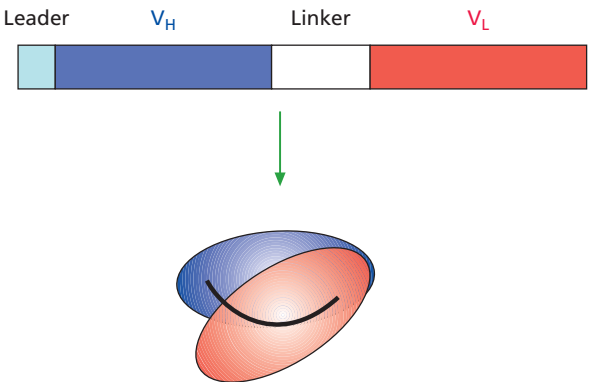

Figure 6 *The single chain Fv (scFv) consists of the V_H and V_L domains of the antibody, stabilized by a peptide spacer between the N terminus of one domain and the C terminus of the other. The molecule is encoded by a single gene, which translates into a single polypeptide chain.*

Table 2 *Half-lives of antibody fragments*

	$t_{1/2\alpha}$ (min)	$t_{1/2\beta}$ (h)
IgG	39	113
F(ab′)$_2$	26	12
Fab′	9.2	88 min
scFv	3.7	90 min

The data taken from Milenic et al. (1991) shows the half-life of different versions of the CC49 antibody. These are given as two phases, the α phase (roughly corresponding to equilibration into the extravascular volume) and the β phase (clearance from the body). The scFv and Fab′ fragments show much more rapid equilibration and clearance.

size, with a very short clearance rate (Table 2) (Milenic et al. 1991) and good penetration of solid tissue. A phage-derived scFv with specificity for carcinoembryonic antigen has been used to image patients with neoplastic disease, with a half-life of around 5 h (Begent et al. 1996). In this case the antibody was better at imaging tumors than conventional antibodies. Similarly, a scFv specific for the C5 component of complement has a half-life of 7–14 h in patients (Fitch et al. 1999).

Other Fv-based molecules have been produced. The main alternative is the disulfide-stabilized Fv (dsFv) (Figure 7). In this molecule single mutations have been made that have changed an amino acid residue on the interface between the two variable domains into cysteine (Glockshuber et al. 1990). The molecules are then free to pair and make a disulfide bond that stabilizes the interaction between the two domains. Clinical trials have been described in which dsFvs fused to toxins have been administered to patients with hematological malignancies (Kreitman et al. 2001).

SMALLER FRAGMENTS

Although the Fv is the smallest fragment of a human antibody that retains an intact antigen-binding site, attempts have been made to decrease the size of recombinant antibodies still further. Although an intact antigen-binding site has six CDRs that can contribute to the interaction with antigen, in many cases not all are needed. Thus, some antibodies show preferential usage of the heavy chain CDRs. This has led to the production of single domain antibodies (dAb), in which just one variable domain (normally the V_H) is produced (Ward et al. 1989). In some cases, dAbs show binding to antigen. However, there are two drawbacks to this approach. The first is that there is likely to be a loss of affinity as half the CDRs are removed. This might be overcome by techniques such as phage display. The major problem is that the dAb contains a surface that is normally hidden by interaction with the other variable domain, and this surface contains hydrophobic amino acids that normally contribute to stabilization of the interaction between the domains. However, in a dAb they can cause the fragment to become highly 'sticky' and also prone to aggregate.

One solution to this has come from the realization that members of the cammelid family (camels and llamas) have antibodies that consist of just the heavy chain (Hamers-Casterman et al. 1993). This feature is

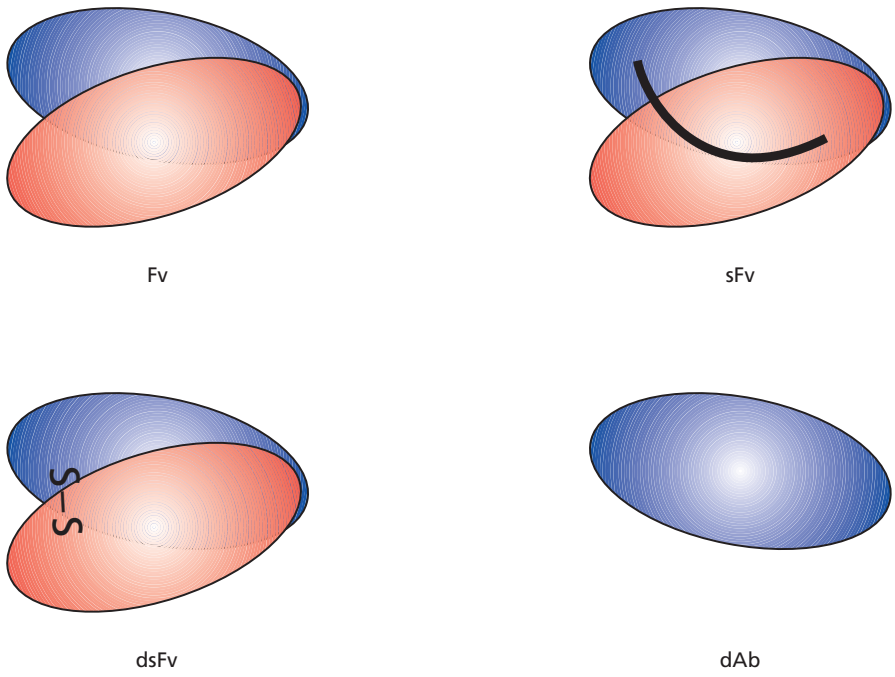

Figure 7 *Other Fv-based molecules: in addition to the scFv other molecules have been made with the aim of exploiting the antigen-binding site of the Fv. These include the disulfide-stabilized Fv (dsFv) in which a disulfide bond in the interface of the two domains prevents the V_H and V_L from dissociating. In addition the single domain antibody (dAb) contains just one domain (normally the V_H).*

also seen in other species such as sharks (Pilstrom 2002). The equivalent surface of the heavy chain variable domain is adapted to working in the absence of a partner V_L, and so is not 'sticky'. It is therefore possible to make dAbs from such species, as well as to consider mutating the human V_H domain to make it more 'camel like' (Davies and Riechmann 1994),

The ultimate in small recognition units is a single CDR. Several groups have devised peptide sequences based on the CDR of an antibody that retains a degree of antigen binding (Zhang et al. 1996; Laune et al. 1997; Park et al. 2000). In most cases these peptides are cyclic, thus somewhat constraining their conformation. In most cases the affinity of the peptides for their antigen is relatively low. However, they are inexpensive to make and can be administered in large quantities to compensate for this. Although it is unlikely that they will replace antibody-like molecules for most targeting purposes, the use of antibody technologies to identify and isolate CDRs that can be used for specialized applications (such as blocking viral entry) is an interesting route to drug development.

Effector functions

The small antibody fragments described above have the ability to target their antigen, but carry no effector function (other than blocking). In addition, most of the fragments described above are monovalent and so are not capable of cross-linking their antigen (and also suffer from a loss of avidity). It is therefore necessary to modify them, normally by fusing them to alternative molecules. In the following section, several examples normally based on the scFv molecule (as that is the most commonly used) are given. However, most of the approaches can also be applied to other fragments (Fab, dsFv, dAb, etc.).

FUSION PROTEINS

The simplest way to endow an antibody fragment with function is to fuse it to the molecule with the desired function (Figure 8) (Neuberger et al. 1984). The scFv is very tolerant of fusions to both the N terminus and C terminus (or indeed both), retaining its affinity for antigen, although this is not always true of the fusion partner.

The partner protein can be just about any protein, including toxins (Chaudhary et al. 1989), enzymes, and cytokines (Boleti et al. 1995), as described earlier for conventional conjugates. They can also be viral coat proteins (e.g. pIII in filamentous phage, see section on Phage display). In some cases it is also possible to use peptides with a function, e.g. a short peptide has been designed that chelates the radioisotope ^{99m}Tc (George et al. 1995b). The scFv incorporating this peptide can, in a single, rapid, one-tube process, bind to and chelate the radioisotope. The interaction is highly stable and allows the site-specific labeling of recombinant scFv (or other proteins), making them highly suitable for imaging applications (George et al. 1995b; Huston et al. 1996b).

RECOMBINANT BISPECIFIC ANTIBODIES

Conventional methods of making bispecific antibodies have been described above, but recombinant antibody fragments also offer very convenient building blocks for making these molecules (George and Huston 1997). A variety of fragments has been described, some of which are shown in Figure 9.

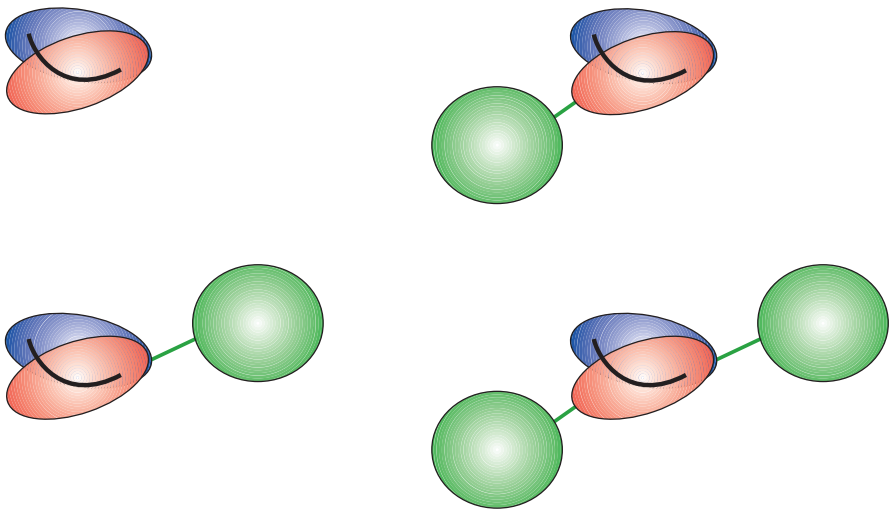

Figure 8 *Fusions with scFv: functional properties can be given to the scFv antibody by fusing the molecule with another protein or peptide (shown in green). This fusion can be N- or C-terminal to the scFv (or even at both ends). In general the scFv is tolerant to such additions, although the function of the effector protein may depend on the orientation.*

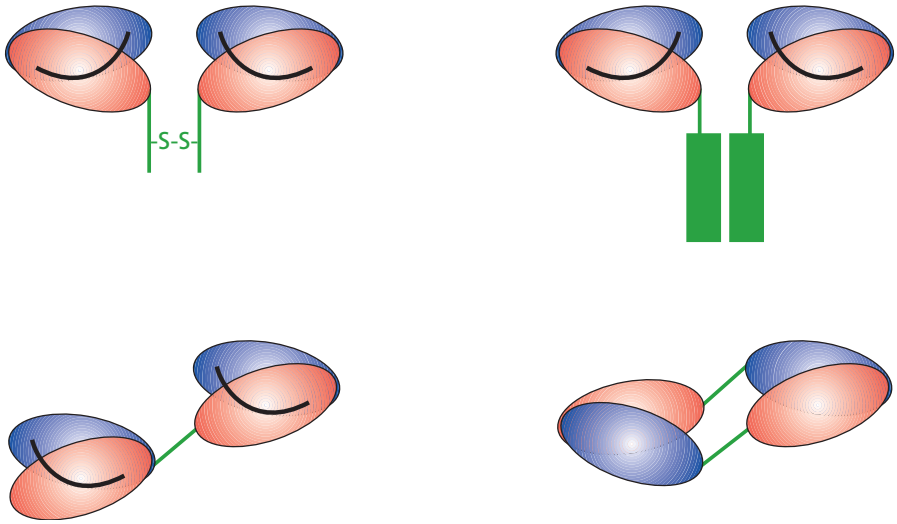

Figure 9 *Recombinant bispecific constructs: there are several ways in which the scFv (or equivalent) antibody fragments can be used to generate bispecific antibodies. These include using disulfide bonds to join two fragments together, fusion to domains (such as leucine zippers) that cause heterodimerization, use of a peptide linker to join two scFvs, or the formation of diabodies in which two polypeptide chains associate in a head-to-tail conformation.*

The simplest approach is to add a cysteine residue to the scFv to allow dimerization (or chemical conjugation) (McCartney et al. 1995). It is possible to fuse the scFv with domains in order to encourage heterodimerization, as opposed to homodimerization. These are often based on leucine zipper motifs, such as jun and fos, which naturally heterodimerize. Fusion of scFv or other antibody fragments with such zippers results in the formation of bispecific antibodies (Kostelny et al. 1992; de-Kruif and Logtenberg 1996).

The second approach is simply to fuse two scFv together, to form a single chain bispecific antibody, which is expressed on a single polypeptide chain. Although this is an elegant approach, in many cases the yields of such molecules are low (Andrew et al. 1991; Huston et al. 1991; Kurucz et al. 1995).

The final approach that is described is the formation of diabodies (Holliger et al. 1993; Whitlow et al. 1994). The scFv molecule is designed with a long enough linker so that the V_H and V_L domains interact with each other. However, if the linker is shortened this is not possible, and in such cases the domains interact with their partner domains on other molecules, forming two chain diabodies. With the appropriate choice of molecule, it is possible to generate bispecific diabodies. Indeed, this approach can be taken further to create trivalent triabodies (Hudson and Kortt 1999).

All of the strategies described above for generating bispecific antibodies can also be used to make bivalent scFv. This might have advantages in terms of the affinity of the interaction with cell surfaces (Adams et al. 1998), and also allow cross-linking of the target molecules and therefore signaling.

MODIFICATION OF TARGET CELLS

The above approaches all rely on administering the recombinant antibody as a protein. However, it is also possible genetically to modify cells so that they express the antibody of interest in a manner that modulates their phenotype or function. One example of this is to express scFv fragments as fusion proteins with molecules involved in signaling (such as the ζ chain of the T-cell receptor (TCR)–CD3 complex) (Eshhar et al. 1993; Eshhar 1997). If such a scFv-ζ fusion is expressed in a T cell, the T cell can become activated upon encounter with the antibody (so-called T bodies). This approach has been applied to other cell types, and may form a useful therapy for neoplastic disease as well as against virally infected cells.

The scFv can also be expressed in an intracellular localization, where they can bind to their antigens. They are directed to the appropriate site by fusion with signal peptides (e.g. KDEL which retains or retrieves the molecule to the endoplasmic reticulum). This can result in 'knocking out' expression of a particular protein or blocking the function of that molecule (Figure 10) (Richardson et al. 1995). However, in the context of infectious disease it can also be used to block viral infection (often termed 'intracellular immunization'). This has been considerably developed in the context of plant infections, but has also been applied to human settings, e.g. in the case of HIV, intracellular antibodies have been generated to a wide range of the viral proteins. Expression of these proteins can prevent functional virions being assembled and so block infection (Mhashilkar et al. 1995; Marasco et al. 1999; Poznansky et al. 1999). This opens the possibility of gene therapy in

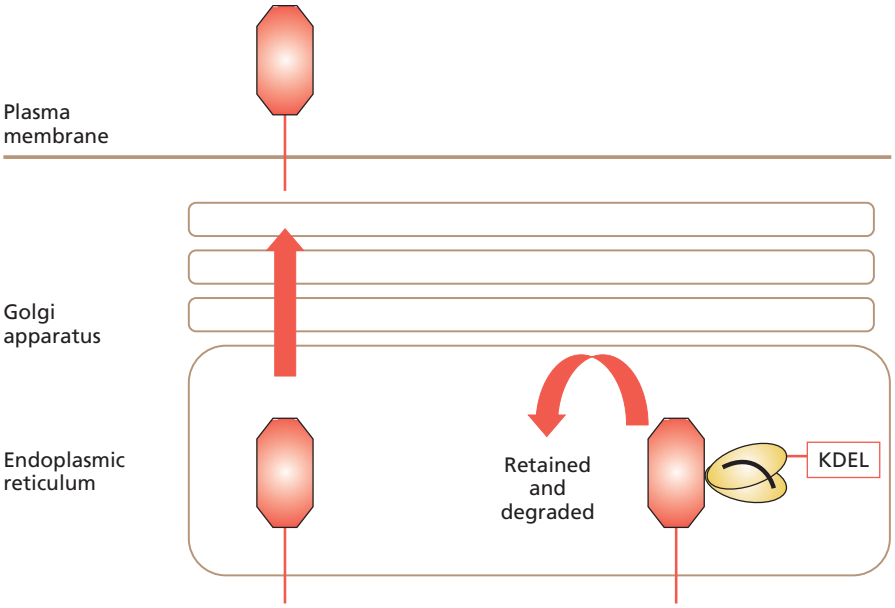

Figure 10 *Intracellular antibodies: normally (shown on left) molecules destined for secretion from a cell or expression on the cell membrane are synthesized in the endoplasmic reticulum. They then pass through the Golgi apparatus to the cell surface. On the right is shown the intervention possible using an intracellular antibody. An antibody (scFv in this example) is expressed in the cell fused to the KDEL sequence. This causes the scFv to be retained in or retrieved to the endoplasmic reticulum. There they bind their target antigen, preventing them from moving to the Golgi and to the cell surface – eventually targeting them for degradation.*

which bone marrow cells are made resistant to infection by expression of intracellular antibodies.

CONCLUSION

A quarter of a century after the description of a generally applicable method for making monoclonal antibodies, they are only now beginning to take their place in the clinic. Why did this process take so long? Many of the reasons were scientific, and the problems and solutions have been discussed above. In addition, there are many commercial obstacles that scientists and clinicians are often rather naïve about, which slow down the development of antibodies (for a fascinating account of the development of one antibody, CAMPATH-1, see Hale and Waldmann 2000). It should perhaps be remembered that it does take time to develop new classes of therapeutic agent. Even penicillin, which is often seen as a remarkable wonder drug that achieved widespread and rapid acceptance, took some time to be developed. Alexander Fleming first noted the death of bacteria on the Petri dish in 1928. It was first tested in patients in 1941 and was in routine clinical use by 1945. This represented a period of scientific advance (including the isolation of the active molecule) as well as industrial development (to produce the product in large enough amounts), which was accelerated by the wartime demands. One of the problems with the cycles of hype and cynicism that surround new forms of therapy is that it can disrupt the steady and sustained effort that is needed to achieve success.

What does the future hold? The current antibodies that have achieved licensing by the FDA are mostly relatively conventional (albeit humanized or chimerized). In the pipeline are the products of phage display and more radical antibody engineering. These are likely to start to make an impact over the next decade, although it is difficult to tell how great this will be. Although the tools of molecular biology do offer really exciting possibilities, it should be remembered that technology developed in the nineteenth century (polyclonal antibodies) is still the most commonly used for the production of clinical reagents. We must adopt the new technologies where appropriate, while not being dazzled by their novelty into applying them in an inappropriate manner.

Introduction	1	MHCII molecules	5
The innate system of defense, APCs, and symbiosis with T cells	2	Stages in antigen presentation	7
Antigen presentation in thymus and peripheral lymphoid organs	4	APC interactions with T cells	9
		References	10

INTRODUCTION

Antigen presentation involves the interaction between the T cell and an antigen-presenting cell (APC) responsible for the uptake and intracellular handling of the protein. All T cells recognize antigen molecules that are presented in the context of histocompatibility molecules. The molecules encoded in the major histocompatibility gene complex (MHC) bind peptides derived from the fragmentation of the protein antigen and present these to T cells. It is the peptide–MHC complex, which constitutes the antigenic determinant, that the T cell recognizes. It follows that all proteins need to be processed by an APC in order for peptides to be generated. Without antigen presentation there is no recognition of the protein by the lymphocyte system (for a historical summary, see Unanue 2002). The two major stable sets of T cells, the CD4 and the CD8 T cells, each recognize peptides that are bound to different sets of MHC molecules. The set of MHC class I (MHCI) molecules present peptides to the CD8 T cells, whereas the MHCII molecules present peptides to the CD4 T cells. The MHCI molecules, examined in (see MHC class I antigen processing system), mainly sample the cytosol of the APCs, whereas in contrast the MHCII molecules preferentially sample the vesicular system. In this way, the MHC molecules contain peptides from proteins that have entered the two major cellular compartments of the APCs. Thus, viruses, intracellular bacteria, or parasites that enter the cytosol are recognized primarily by the CD8 T cells which recognize the peptide antigen–MHCI complex (Rock and Goldberg 1999; Yewdell and Bennink 1999). In contrast, soluble proteins or proteins derived from phagocytosed organisms are presented to CD4 T cells that recognize the peptide–MHCII complex. There are other MHC molecules expressed in lower amounts which can present certain unique molecules, e.g. the MHCI-like molecule H-2M3, binds to small hydrophobic peptides that contain formlymethionine at its amino terminus (Lindahl et al. 1997). The CD1 molecules bind to glycolipids, including those derived from *Mycobacterium tuberculosis* (Porcelli et al. 1992). T cells directed to these MHC complexes may have a role in antimicrobial immunity. This chapter, based on a previous review (Unanue 2001), considers antigen processing and presentation by the MHCII molecules.

It is important, in the context of microbial immunity, to understand how the immune system has evolved to deal with either protein or polysaccharide antigens. The former involve the T cells, as indicated above, by recognition of products of antigen processing, as well as B cells, which can recognize the proteins before catabolism. The end result of a productive encounter with protein antigens is both the production of antibody and the development of a T-cell response – cellular immunity. The T-cell response is long-lived and heightens on repeated immunization, a fundamental feature of prophylactic immunization – the recall response associated with immunization. With the T-cell response

Table 1 *Responses to carbohydrates and protein antigens*

	Pure polysaccharide	Protein
B-cell recognition	Yes	Yes
T-cell recognition	No	Yes
Binding to MHC molecules	No	Yes
Activation of CD4 T cells	No	Yes
T-cell memory	No	Yes
Delayed sensitivity response	No	Yes
Antibody affinity changes	No	Yes

there follows the capacity to activate macrophages and to form the immune granulomas. An important clinical demonstration of the T-cell response is the 'delayed sensitivity' skin reaction that takes place on injection of a minute amount of the antigen into the skin of the immunized individual. This small indurated lesion indicates that the patient has encountered the microbe, and has activated T cells. With regard to the B-cell response, it is characterized by high-affinity antibodies of the various subclasses, which is an indication of affinity-driven maturation by T-cell 'help'.

In contrast, pure carbohydates do not stimulate T cells and only induce a B-cell response that is limited in the range of its response. Immunological memory is poor. There is no delayed sensitivity response. The antibody response shows poor affinity maturation and is mostly represented by IgM antibodies.

This difference in T-cell responses between proteins and pure polysaccharides is explained because carbohydrates do not interact with MHC molecules (Harding et al. 1991; Ishioka et al. 1992). Without an MHC molecule to serve as a carrier of the foreign entity, T cells will not recognize it. Knowing this difference, vaccines against bacterial polysaccharides are now produced by conjugating the carbohydrate to an immunogenic 'carrier' protein, in order also to elicit a T-cell response (Schneerson et al. 1980; Insel and Anderson 1986). Table 1 compares both responses.

THE INNATE SYSTEM OF DEFENSE, APCS, AND SYMBIOSIS WITH T CELLS

The APC cellular system is essential for antigen presentation. Three main cells are involved in presentation; two are derived from the monocyte lineage: the dendritic cells (DC) and the macrophages. They belong to the 'innate' cellular system that operates independently of the lymphocyte lineage (Janeway and Medzhitov 2002). These cells sample and handle moieties from the extracellular milieu, and are therefore essential APCs. The second APCs are the B cells which are involved in the interaction with CD4 T cells during antibody formation.

There is an intimate, truly symbiotic relationship between the innate cellular system and the lymphocyte (Unanue 1981, 1997). The innate system is represented by cells of monocyte lineage: the granulocytes and the natural killer (NK) cells. Only those cells derived from the monocytes are APCs. The cells of the innate system sample the environment, constituting the earliest system of defense that reacts to the presence of diverse pathogens. The innate system is phylogenetically older and represented by the amebocytes and phagocytes of invertebrates (Hoffmann et al. 1999). This is the cellular system first described by Metchnikoff in his classic studies of the phagocytes as an essential defense cellular system (Metchnikoff 1968). In vertebrates, the innate system can effectively handle a number of pathogens but it is incapable of resolving the infections entirely, and importantly will show the property of neither specificity in recognition nor immunological memory.

The phagocytes recognize many bacteria and microorganisms through 'pattern recognition' in which the polysaccharides, lipoproteins, and other moieties are seen as a whole (see Pattern recognition). Phagocytes contain a number of cell surface molecules that allow them to handle a wide range of pathogens (see below). Phagocytes, and in general the cells of the innate system, obey chemical signals from a variety of secreted polypeptides – the family of cytokines and chemokines produced by the lymphocytes (Buchmeier and Schreiber 1985; reviewed in Luster 2002). As a result, the innate system heightens its capacity to deal with, and eliminates, a number of pathogens once the lymphocyte enters the scene. The lymphocyte system, on the other hand, can effectively eliminate pathogens, have exquisite specificity of recognition, and importantly shows memory – the basis of prophylactic immunization. The operation is, however, truly symbiotic, inasmuch as the lymphocyte is blind to antigens unless the antigen molecules are presented by the phagocytes (referring to DCs and macrophages), by way of their MHC molecules, during antigen presentation. During handling of the antigen molecules, the phagocytes also release a number of cytokines, which help in the early recruitment and activation of the lymphocytes (Hsieh et al. 1993) (Figure 1). As the phagocyte system needs to be 'activated' through a number of cytokines elaborated by the lymphocytes, the loop of cell-to-cell interaction is evident, each cell critically depending on the other. The communication between the two interacting cellular systems is by way of antigen presentation via MHCII molecules as well as by cytokines. It is antigen presentation that imparts specificity to the system because the recognition of the presenting antigens recruits the specific clones of T cells. A comparison of the two recognition systems is shown in Table 2.

A highly informative experimental model of infection that brings out the symbiotic relationship between the innate and adaptive system is that of *Listeria mono-*

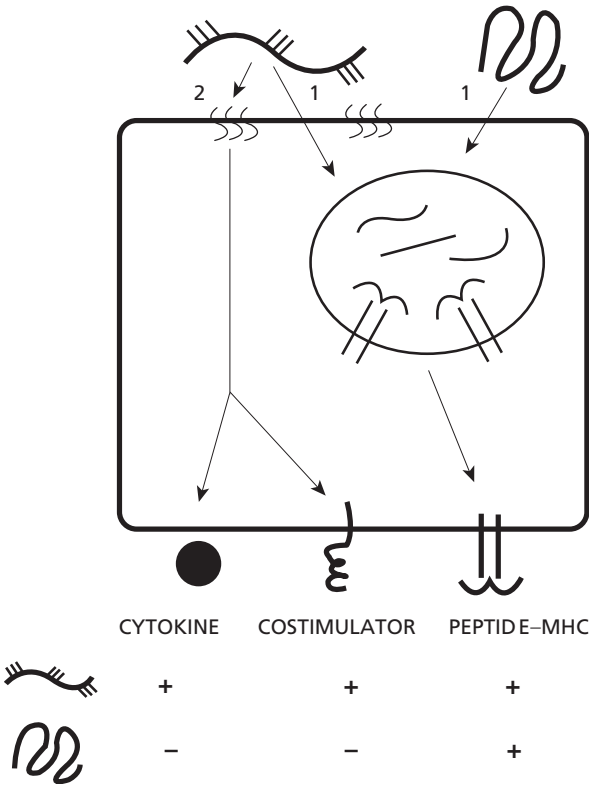

Figure 1 *Graphic representation of the results of two kinds of interactions of an antigen-presenting cell (APC). A bacterium (left side, top) will generate peptides after it is internalized (pathway indicated as 1), but will also activate (pathway 2) Toll-like receptors (TLRs). Pathway 1 will yield peptide–MHC complex to T-cell recognition. Pathway 2 will result in secretion of soluble cytokines and the presence of membrane costimulatory molecules. All three components are required for optimal T-cell activation. A protein (right, top) will give rise to peptide–MHC complex after it is processed, but will not induce cytokine or costimulation and will not productively activate T cells.*

cytogenes infection in the inbred mouse (Mackanness 1962; reviewed in Unanue 1997). *Listeria* species is an intracellular pathogen that is taken up by macrophages where it escapes from the phagocytic vacuole to multiply in the cytoplasm. *Listeria* infection proceeds through various stages: first there is an early neutrophil component that partially contains the growth particularly in the liver; this is followed by a phase in which the macrophages curb *Listeria* replication while also releasing inflammatory cytokines such as the interleukins IL-1, IL-12, and IL-18 and tumor necrosis factor (TNF). These cytokines then lead to an activation of various cells including NK cells as well as CD4 and CD8 T cells. The last are activated by presentation of *Listeria* antigens and then participate in the complete elimination of the bacteria. Mice that only have an innate system, as happens in mice with the severe combined immunodeficiency (SCID) mutation, which lack lymphocytes, will not result in sterilizing immunity although the growth of *Listeria* monocytogen is partially contained. SCID mice will become carriers of the infection but will eliminate *Listeria* sp. completely if reconstituted with T cells. Both CD4 and CD8 kill *Listeria* monocytogen found in phagocytes or epithelial or mesenchymal cells.

With regard to APCs, four conditions are required for them to be effective in antigen presentation. First, the cells must have the capacity to take up proteins, which they do by various molecular systems. Second, the APCs must have the internal cellular machinery to enable them to process proteins. All cells have a lysosomal system that allows them to handle endocytosed proteins. Thus, as far as their capacity to present is concerned, it will depend to a major extent whether the MHC molecules are expressed. Indeed, many cell lines that do not express MHCII molecules will do so if transfected with the genes encoding MHC genes. Lastly, for effective antigen presentation APCs must also express other molecules that allow for stimulation of the T cell.

Dendritic cells derive from the blood monocyte and inhabit many tissues, where they are highly effective in antigen presentation (Inaba et al. 1983; Banchereau and Steinman 1998; Lanzavecchia and Sallusto 2001; Guermonprez et al. 2002). DCs circulate in small numbers in blood and are rapidly mobilized to sites of infection. Monocytes also differentiate to DCs as they cross into the tissues. In the lymphoid organs, DCs constitute a network of interdigitating cells located mainly in the deep cortex of the lymph nodes, or the periarteriolar sheath of the spleen. DCs express receptors for some chemokines such as CCR7 which regulates their migration into lymphoid organs (Tang and Cyster 1999). DCs are found in the skin, as Langerhans' cells, situated between the keratinocytes: on interaction with antigens that contact the skin, they migrate into the draining node and there recruit specific T cells. DCs are also found in the thymus where they play a vital role in the process of presentation of autologous proteins. DCs are divided into two subsets called myeloid and lymphoid,

Table 2 *Comparison of innate and adaptive immunity*

	Innate	Adaptive: B cell	Adaptive: T cell
Antigen recognition	Nonclonal	Clonal	Clonal
Antigen receptors	Many	Single	Single
MHC involvement for recognition	No	No	Yes
Memory	No	Yes	Yes

A clonal system refers to B and T cells, each of which express only one set of antigen receptors having unique specificity. The adaptive system is therefore a selection by antigen of those B and T cells with receptors of high affinity. The cells of the innate system can identify more than one foreign antigen.

distinguished by the presence of the C8 α protein, in the latter.

Dendritic cells are highly effective in interacting with T cells (Lanzavecchia and Sallusto 2001). Their expression of both class I and II MHC molecules is high and constitutive. DCs also express adhesion and costimulatory molecules. DCs show long cytoplasmic extensions which favor the intimate physical contact with T cells. DCs can be generated from bone marrow cells in the presence of the cytokine granulocyte–macrophage colony-stimulating factor (GM-CSF) (Inaba et al. 1992; Sallusto and Lanzavecchia 1994). These in vitro cells can present antigens and have been used in transplantation studies to immunize, particularly in cancer immunotherapy (Nestle et al. 2001).

Dendritic cells evolve through various stages of maturation (Thery and Amigorena 2001; Guermonprez et al. 2002). The immature DCs express low levels of adhesion and costimulatory molecules, although their processing of antigens is not impaired. On interaction with a variety of stimuli, DCs increase their expression of the adhesion and costimulatory molecules and become more effective in antigen presentation. Among the stimuli are cytokines such as TNF-α or IL-1, both gram-positive and -negative bacteria, and their products, such as endotoxins, double-stranded RNA, and interaction with the CD40 ligand (Inaba et al. 1993; Cella et al. 1996, 1999; Randolph et al. 1998).

Macrophages were the first cells to be identified as APCs (Unanue 2002). Derived from monocytes by way of interaction with the cytokine CSF-1 (or M-CSF), macrophages inhabit many tissues, particularly around blood vessels where they sample the extracellular fluid (see Phagocytes part 1: macrophages). Macrophages have an important effector function in their uptake and handling of microbes. Their microbicidal activity is readily enhanced by contact with cytokines particularly with interferon-γ and TNF. Macrophages secrete a large number of important cytokines that are involved in the early stages of an immune response. Macrophages differentiate in tissues influenced by the local environment of the tissue. They express low levels of MHC molecules and their antigen-presenting function can be limited unless activated by interferon, which markedly increases their expression.

B cells express constitutively both class I and II molecules and have an important antigen-presenting role in the interaction with CD4 T cells (Chesnut et al. 1982; MacPherson et al. 1999). This interaction leads to antibody formation in a two-step process: first, B cells bind the antigen by way of their specific membrane-bound antibody (Lanzavecchia 1990), after which the protein is processed, leading to the expression and presentation of the peptide–MHC complex; second the cloned T cell then recognizes the complex leading to their reciprocal activation. The final result is a reciprocal activation of both cells: the T lymphocyte will continue its activation while the B cell proliferates and differentiates, evolving into an antibody-forming cell. The end product is the release of antibody molecules that are identical in their specificity to the original antibody on the B-cell surface. These antibodies can be directed to conformational determinants of the protein. Thus, the result is the release of antibodies to conformational determinants of the protein and T cells that recognize linear sequences of the same. Immature B cells have limited antigen-presenting capacity, which increases as the B cell is activated.

ANTIGEN PRESENTATION IN THYMUS AND PERIPHERAL LYMPHOID ORGANS

Antigen presentation takes place during the response to foreign molecules that enter the tissues, including the lymphoid tissues. The encounter of the phagocytes with antigen results in the selection of T cell, with complementary receptors to the peptide–MHC complex displayed on the APC surface. The exact events involve several steps where cytokines and chemokines are released, resulting in increases in vascular permeability and cell migration to the foci of antigen–APC interaction. The end result is the recruitment of the antigen-specific T-cell clones, leading to their proliferation and the release of cytokines. Clonal enlargement results in an increase in specific lymphocytes and a more effective process for elimination of the foreign antigen. The cytokines released by T cells markedly influence the cellular environment, fostering growth and differentiation as well as activation of phagocytes. From this process, the phagocytes change their behavior to a cell more active in cytocidal activity and capable of eliminating a range of microorganisms.

T cells also encounter peptide–MHC during their normal process of maturation in the thymus gland. The nature of this encounter is very different from that described above, in that the peptides that form the complex do not derive from foreign molecules (which normally do not enter the thymus gland), but from the processing of self-proteins. It is this encounter that influences the fate of the early T cells during its normal process of differentiation. The thymus contains in its cortex a network of epithelial cells that express MHCII molecules (in contrast to most epithelial cells which do not). It also contains DCs particularly in the area between cortex and medulla, and in the medullary area itself. As the thymocyte matures, it expresses by random rearrangements of its receptor genes, antigen receptors (T-cell receptor (TCR)) that may or may not have specific complementarity to the autologous peptide–MHC complexes. This normally engages amino acid residues from the peptide, and also segments of the MHC molecules itself, around the area that binds the peptide. Thus, it is a receptor with a dual specificity (Garcia et al. 1996; Garboczi et al. 1996; Reinherz et al. 1999).

Three developments take place during the differentiation of the T cell, depending on the nature of the TCR and the MHC molecules with which it can interact (reviewed in von Boehmer 1990; Robey and Fowlkes 1994; Jameson et al. 1995; Borowski et al. 2002). A T cell with a TCR that does not match or complement the autologous peptide–MHC dies by 'neglect'. A T cell that encounters a perfect match will also die, a process called 'negative selection' (Kappler et al. 1987; Kisielow et al. 1988a, 1988b). Through this negative selection event, a number of autoreactive T cells are eliminated and therefore autoimmunity is prevented. In both these processes the T cell dies by apoptosis. Finally, a T cell with a receptor that matches the MHC, but matches the peptide poorly, matures, leaves the thymus, enters the recirculating pool of blood T cells, and seeds the lymphoid organs (Kisielow et al. 1988b). This process of 'positive selection' results in the survival and selection of T cells with TCRs that interact with self-MHC molecules, and particularly with peptides other than the autologous ones presented in the thymus, i.e. peptides from foreign proteins.

This process of T-cell maturation, in which T cells are selected to recognize a peptide and its own MHC molecule, explains the important phenomenon known as 'MHC restriction', which is characteristic of antigen presentation (Rosenthal and Shevach 1973; Zinkernagel and Doherty 1974). The mature T cells only recognize peptides derived from proteins presented by an APC that displays its own MHC molecules. In an outbred population, where the MHC shows marked allelic polymorphism, a T cell with specificity for a protein processed by its own APCs will not recognize the protein presented by an APC of a different individual. The fundamental reason is that the T cell is constrained as a result of the nature of the thymic selection process in recognizing its own MHC proteins. The phenomenon of MHC restriction was discovered for both CD4 and CD8 T cells when antigen-specific cells from one inbred strain of experimental animals were combined in culture with APCs of strains with different MHC alleles. (The experiments that discovered restriction in the MHCII molecule are shown in Table 3.) The same results were obtained when studying T- and B-cell interactions (Katz and Unanue 1973). Apart from the fact that this phenomenon was instrumental in pointing to the basic rules of APC–T-cell interaction, it also has practical applications. The clinical relevance is to the use of antigen-specific T cells for immunotherapy of patients with infectious diseases. For example, specific T-cell clones that can be generated ex vivo will not be useful unless they are transplanted in individuals who share the same MHC alleles.

MHCII MOLECULES

Every species contains an MHC gene complex that encodes for a number of class I and class II molecules. In humans, the complex is the HLA gene complex encoded in chromosome 6. The HLA gene complex includes genes that encode for the α and β chains of MHCII molecules, for the heavy chain of several MHCI molecules and genes for several complement proteins. The MHCII molecules contain two transmembrane chains, termed α and β, that assemble to create the peptide-binding site. The MHC of the mouse is H-2, discovered first by transplantation biologists who identified it as a system of cell-surface antigens with multiple alleles, responsible for tissue rejection.

The major function of class I and II molecules is to bind peptides, creating the complex that forms the substrate for T-cell recognition (Babbitt et al. 1985). One important feature of the MHC gene complex is its large degree of allelic polymorphism. The allelic differences are accounted for by several amino acids located in the region of the molecules that bind to peptides. The evolutionary pressure for diversification of the MHC and its selection is probably accounted for by microbial and parasitic infections (reviewed in Klein et al. 1993; Dawkins et al. 1999; Parham 1999). The argument goes

Table 3 *Rosenthal–Shevach experiment showing major histocompatibility complex (MHC) restriction for the presentation of purified protein derivative (PPD)*

Macrophages		T lymphocytes (cpm × 10^{-3})		
Strain	**PPD**	**Strain 2**	**Strain 13**	**Strain (2 × 13) F1**
2	–	0.9	5.7	1.6
2	+	26.4	8.6	7.0
13	–	4.6	1.7	1.8
13	+	3.1	19.9	7.8
(2 × 13) F1	–	1.9	4.3	1.7
(2 × 13) F1	+	12.4	11.8	12.6

The two inbred strains of guinea pigs, named 2 and 13, differ at their class II MHC gene locus. The guinea pigs were immunized with dried tubercle bacillus in water in oil emulsion. Their T cells were isolated and cultured with macrophages from normal guinea pigs, in the absence or presence of PPD of *Mycobacterium tuberculosis*. Strain 2 lymphocytes responded only to PPD presented by macrophages of strain 2, and the same applied to lymphocytes from strain 13. Note the mild mixed lymphocytic reaction when lymphocytes from 2 or 13 are incubated with macrophages of strains 13 or 2, respectively. Modified from Rosenthal and Shevach (1973).

that the more polymorphism there is in the species, the more the diversity of peptides is selected from microbes, and the better protected is the species to face infectious agents. Examples are known of HLA alleles favoring protection against malaria and leprosy (Piazza et al. 1973; Hill et al. 1991). Conversely, situations in nature that have reduced MHC polymorphism translate into enhanced susceptibility to infection (O'Brien and Yuhki 1999). This occurs in some examples of cheetahs, tigers, and Florida panthers (O'Brien and Yuhki 1999).

MHC molecules are peptide-binding molecules that select peptides from intracellular digestion of the protein (Babbitt et al. 1985; Bjorkman et al. 1987b; Unanue 2002). Both MHC molecules contain a single binding site that accommodates peptides of varying lengths. The MHCI molecule is made up of a single transmembrane glycopolypeptide – a heavy chain of about 44 kDa that folds in its amino terminus to create the binding site. It also contains a small polypeptide called β_2-microglobulin that gives structure to the heavy chain. The MHCII molecules contain two extracellular transmembrane chains, α and β, of about 20–30 kDa, which together create the binding site. The binding site of both class I and II molecules is similar with a platform of β-pleated sheets and two helical walls, between which is located the peptide (Bjorkman et al. 1987a, 1987b; Stern et al. 1994; Madden 1995).

Each MHC molecule binds one peptide, usually in the range of a nanomolar or micromolar affinity constant. The interaction of MHC molecules with peptides has been studied in binding interactions using purified molecules and peptides (Babbitt et al. 1985, 1986; Buus et al. 1987a, 1987b). By creating single or multiple changes in the composition of the peptides, the specificity of the interactions and the contributions of a given residue to binding strength can be determined. Peptides usually bind with a slow on-rate but, once bound, the dissociation rate from the complex is slow. It translates into peptides in the live APCs being maintained for a relatively long period of time.

The structural studies of MHC molecules containing peptides are important for understanding the nature of the binding (Brown et al. 1993; Stern et al. 1994; Fremont et al. 1998a, 1998b; Scott et al. 1998; Latek and Unanue 1999). In the MHC molecules, the various residues responsible for the allelic differences are situated in sites combining class I and II MHC molecules. These various residues constitute allele-specific binding sites or 'pockets' which accommodate different amino acids from the peptide. For each MHC allelic form, there are usually four to five sites: P1, P4, P6, P7, and P9. These accommodate the various side chains of the peptide, which is stretched through the combining site. For many alleles one or two of these pocket sites are mainly responsible for both binding the peptide and its specificity. The binding results from two main interactions, that of the peptide amino acid side chains with the pockets and that of the peptide backbone with conserved residues of the MHC binding sites, through which a large network of hydrogen bonds is created (Chicz et al. 1992; Hammer et al. 1992; Hunt et al. 1992; Sinigaglia and Hammer 1995; Suri et al. 2002).

What are the features of peptides presented by the class II molecules that CD4 T cells recognize? Peptides presented by class II MHC molecules are usually longer than 10 amino acids whereas those presented by class I are eight to nine residues in length. The peptides contain a 'core' of nine amino acids and flanking residues of varying lengths (reviewed in Latek and Unanue 1999). In the peptide core sequence, some amino acid side chains interact with the allele-specific pockets, mentioned above. The flank residues are important in contributing to binding strength and to the stability of the MHC–peptide complex. Class II peptides vary in the length of their flanks; in fact many peptides are selected as families made of the core with flanks of varying length. Two to three amino acid side chains of the peptide are solvent exposed and potentially capable of binding to the TCR.

It is important to note that the MHC molecules bind to self and foreign peptides equally well (Babbitt et al. 1986). This is evident from the description of thymic maturation, which involves interaction with self-peptides. It follows that, because self-proteins are always normally being processed, there is always the potential to develop autoimmunity. Indeed, a series of autoimmune diseases are known to develop in which autoreactive T cells recognize self-peptides bound to MHC molecules.

The process of protein processing and presentation between class I and II molecules differs in important respects. Suffice it to state here that class I molecules have evolved to recognize peptides resulting from cytosolic catabolism, which are then taken into the endoplasmic reticulum where the complex is assembled (Townsend et al. 1986). Class II molecules, as indicated before, mainly recognize peptides derived from the intravesicular processing and are loaded in acid lysosomal-like compartments. The nature of the peptides recognized by both systems differs.

Peptides bind with different degrees of affinity, depending on their constellation of amino acid side chains and the nature of the particular class II molecule. Some do not bind at all and to these the immune system will not mount an immune response (Levine et al. 1963; McDevitt and Sela 1965; reviewed in Benacerraf 1981; McDevitt 2002). It is the fact that some MHC alleles bind peptides poorly whereas others bind strongly that led to the discovery of the role of the MHC gene complex in the immune response. The MHC had been previously examined only in the context of nonphysiological reactions, those of tissue transplantation. When studying responses to small polypeptides of limited heterogeneity, it soon became apparent that some inbred strains of mice responded strongly whereas others made poor responses

(McDevitt 2002). Such a trait was found to be autosomal dominant and mapped to H-2, and in particular to a new region, later found to encode for the murine class II molecules (McDevitt and Chinitz 1969). These studies were seminal in calling attention to the importance of H-2 in regulating immune responses to proteins.

The nature of the peptides bound to MHC molecules during processing can now be studied by electrospray tandem mass spectrometry (Chicz et al. 1992; Hunt et al. 1992) (Figure 2). MHC molecules are isolated from APCs and denatured to release the peptides, which are then analyzed and sequenced. One can identify peptide families with as many as 40 members, and some represented in very large amounts (Latek and Unanue 1999). This approach has now been used to identify the precise peptides selected during the processing of viruses and bacteria. Examination of peptides selected by different MHC alleles indicates the preference for each allele to select peptides based on particular sequence motifs. These motifs are based on the presence of amino acids in which side chains enter into interaction with the specific binding loci. For any given protein, some peptide segments are selected during processing and bound to the MHC molecules whereas others are not recognized or recognized very weakly, and rapidly dissociate.

The peptides bound to MHCII molecules derive from extracellular proteins, as expected. Most peptides derive from the processing of membrane proteins, e.g. transferrin receptor or invariant chain, or even from the α and β chain of the class II molecule itself. Peptides also derive from proteins of the cytosol. These probably enter the vesicles by autophagy.

As the peptides bind to class II molecules, a number of the side chains of their component amino acids become solvent exposed and can potentially contact the TCR (Allen et al. 1987). In class II-bound peptides, these solvent-exposed residues are consistently placed at the P1, P2, P3, P5, and P8 positions (the MHC anchors placed at P1, P4, P6, P7, and P9). The TCR interacts with some of the residues of the solvent-exposed residues. Their interactions tend to be of low affinity. Structural studies indicate that both the peptide and the MHC are contacted by the two chains of the TCR (Garboczi et al. 1996; Garcia et al. 1996; Reinherz et al. 1999; Hennecke and Wiley 2001; Rudolph and Wilson 2002). The TCR adopts a canonical conformation in which its long contact axis is diagonal or orthogonal to the peptide–MHC. Part of the TCR contacts the helices of the MHC, particularly the complementary determinant regions (CDR) 1 and 2, which are germline encoded. (The CDRs are the regions of the TCR responsible for their binding specificity.) On the other hand, the CDR3 segment, where extensive variations exist, contacts the middle regions of the peptide. The structural studies have therefore validated the concepts derived from the findings of MHC restriction that the TCR has double specificity, one for the MHC, another for the peptide. One interpretation is that the contacts of CDR1 and CDR2 are responsible for positive selection, whereas it is CDR3 interaction that offers the peptide specificity.

STAGES IN ANTIGEN PRESENTATION

There are several stages in presentation. The antigen molecules need to be taken into vacuoles where they are processed, resulting in the generation and display of the

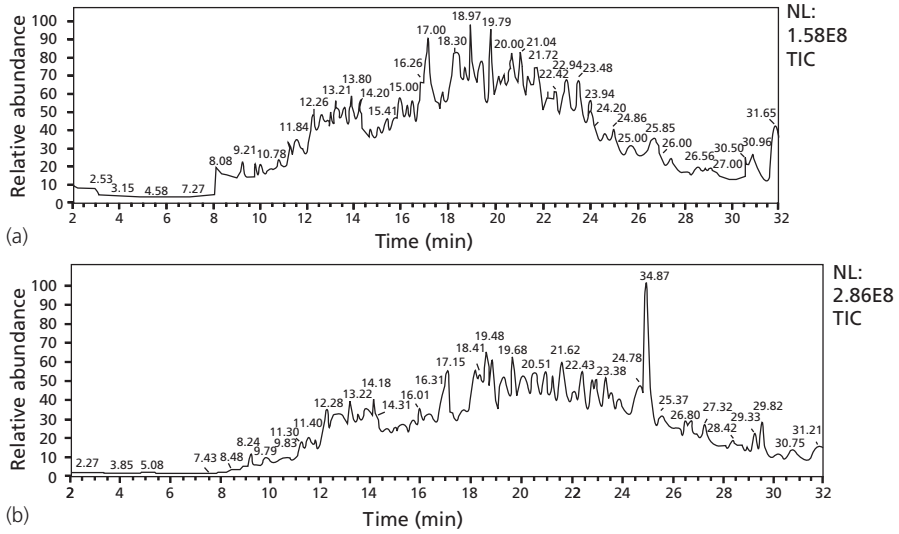

Figure 2 *Biochemical analysis of peptides extracted from the class II MHC molecule I-A . The two panels represent the separation of peptides by reverse phase chromatography. The top panel indicates the many peptides are bound to class II molecules. In the lower panel, the antigen-presenting cells (APC) were given lysozyme. Note the large peak at 25 min: it is the dominant peptide processed from lysozyme. (Redrawn from Gugasyan et al. 2000, with permission.)*

peptide–MHC complex. Following the display, there is the encounter with the T cells that have receptors specific for the complex. Recognition by the T cell is followed by activation depending on a number of important variables.

Antigen-presenting cells can present peptides from free proteins, or from proteins that form part of the structure of microbes or unicellular organisms. APCs can also interact directly with peptides found in extracellular fluids, and can also present proteins from cells or cell material that has been phagocytosed. (The term 'crosspresentation' or 'crosspriming' has been used to describe T-cell activation by a cell that lacks MHC molecules, but can be taken up when dead by an APC, which then presents its antigens.)

Protein antigen can enter the APC by fluid phase endocytosis or by ligand receptor internalization (reviewed in Unanue 2001). Under both conditions, the internalized protein eventually encounters the MHCII molecules, although the amount of uptake is favored in the case of receptor-mediated uptake. Uptake of viruses, bacteria, or other pathogens can be mediated by a variety of receptors such as the Fc and the complement receptors; or other surface receptors such as the scavenging receptor or those that recognize various polysaccharides. Together with bacteria, an important component of the recognition is the Toll-like receptor (TLR) (Medzhitov et al. 1997; Takeuchi et al. 1999; reviewed in Krutzik et al. 2001; Janeway and Medzhitov 2002). TLRs are involved in signaling during the interaction of the bacterium or its products with the surface of the phagocytes. Each TLR has a preference for the microbial ligands.

For B cells, the receptor for the protein antigen can be the specific membrane-bound immunoglobulin (Lanzavecchia 1990). Uptake by specific B cells can increase the efficiency of presentation by about a 1000-fold over uptake by fluid phase endocytosis. It is the uptake of antigen by specific immunoglobulin of B cells, and the subsequent presentation of its peptides to T cells, that form the basis of B cell–T cell interaction that leads to antibody formation.

The processing of proteins and the loading of MHC molecules with peptides are fast events (Table 4). Usually by an hour or less after uptake, complexes of peptide and MHCII molecules can be found on the cell surface (Ziegler and Unanue 1981; Cresswell 1994; Watts 1997, 2001). The proteins are usually processed in deep vesicular compartments of the APC, which are rich in lysosomal proteases as well as having a reducing activity. A number of lysosomal proteases are involved in the proteolytic processing (reviewed in Villadangos et al. 1999; Watts 2001). Alkalinization of the acid proteases of the APC results in inhibition of antigen processing (Table 4). The protein antigens have to be denatured and/or partially fragmented before interaction with MHC molecules. A scenario is that the protein, or a large polypeptide derived from it, is unfolded, after which the MHC binds to a preferred segment. The peptide segment is then protected from catabolism (Donermeyer and Allen 1989). Enzymes with amino- and carboxy-peptidase activity proceed to trim the segment of the polypeptide that extends beyond the combining site (Nelson et al. 1997). The reduction and partial fragmentation of the protein give it sufficient conformational flexibility to allow for binding to class II molecules. Although peptides and partially denatured proteins can be bound by class II molecules, most globular proteins in their native state do not bind. As indicated in Table 4, peptides can bind to class II molecules and these do not require any further handling. In fact, peptides can bind to surface MHCII molecules directly.

Proteins that are denatured meet the nascent MHCII molecules, recently arrived from the endoplasmic reticulum (ER) via Golgi vesicles (reviewed in Pieters 2000; Unanue 2002). The lysosomal vesicle that receives the antigen also receives the nascent MHCII molecules. MHCII molecules are transported from ER–Golgi to the loading vesicle together with another polypeptide called

Table 4 *Experiments indicating the processing of protein antigens for class II major histocompatibility complex (MHC) presentation*

Antigen-presenting cell display					
Protein	**Peptide**	**Time (min)**	**Treatment**	**Fixation**	**Peptide–MHC**
1 +	–	0	–	–	No presentation
2 +	–	60	–	–	++++
3 +	–	60	Chloroquine	–	+/–
4 +	–	60	–	Fix at time 0	No presentation
5 +	–	60	–	Fix at 60 min	+++
6 –	+	0	–	–	+++
7 –	+	0	Chloroquine	–	+++
8 –	+	0	–	Fix at time 0	++

A protein antigen requires a period of time (indicated as 60 min) before presentation takes place to T cells. Inhibition of intracellular proteolysis by alkalinization of the vesicular pH by chloroquine inhibits presentation (no. 3). Cells that processed the protein and displayed it in their surface MHC molecules can be fixed and still present to T cells (no. 4). Peptides do not need processing (nos 6–8).

the invariant chain (so called because it does not show the allelic polymorphism of the class II molecules). The invariant chain is about 33 kDa, but shows some heterogeneity, with post-translational changes and various different splicing forms (Cresswell 1996). Three invariant chain forms a complex with three α–β dimers of MHCII. The function of the invariant chain is to direct the MHC molecule to the loading vesicle (Lotteau et al. 1990). It also folds over the peptide-binding site, and in this way blocks the binding to it of peptides found in the ER (Roche and Cresswell 1990). Once the proteins arrive at the loading vesicle, the invariant chain is degraded by acid proteases, particularly involving cathepsin S (Riese et al. 1996), liberating the peptide-binding site of the class II molecules, which can then receive peptides from its surrounding (Villadangos et al. 1997).

Peptide loading is markedly favored by a second MHC-like molecule named HLA-DM (Cho et al. 1991; Kelly et al. 1991). DM interacts with class II but does not bind peptides (it is also made of two chains, but has a combining site that is closed) (Fremont et al. 1996; Mosyak et al. 1998). The function of DM is a catalytic one, favoring the rapid dissociation of weak peptides and fostering the binding and stability of strong binding ones. In this way, DM serves to edit peptide selection, favoring the binding of peptides with strong affinities (Morris et al. 1994; Sloan et al. 1995).

Finally, it should be noted that microbes affect intracellular processing, attempting to divert the presentation to T cells. One mechanism is to inhibit fusion of the phagocytic vacuole with lysosomes avoiding processing. This inhibition occurs most notably with *Mycobacterium tuberculosis* (Armstrong and Hart 1975; Ferrari et al. 1999). A number of viruses affect primarily the processing by way of MHCI presentation.

APC INTERACTIONS WITH T CELLS

T cells contact the APC bearing the peptide–MHC complex and establish firm contact that lasts for several hours. During the time of contact, molecular events take place in the T cell that lead to their activation. This contact is in the immunological synapse. At the synapse, there is an early and rapid rearrangement of the TCR, and its accompanying components, with their coalescence into a tight compact area (Shaw and Dustin 1997; Grakoui et al. 1999; Shaw and Allen 2001; Krummel and Davis 2002). Likewise, the peptide–MHC complex of the APC also reorganizes into a single large aggregate. In the synapse, the TCR moves towards the center of it whereas molecules that favor adhesion, such as the intercellular adhesion molecule (ICAM), move towards the periphery of the complex. This segregation of the membrane molecules allows for effective contact of each of the complementing pairs of molecules of the T cell and the APC. The relatively small TCR and the peptide–MHC spans about 12 nm, whereas very large molecules such as CD43, CD44, and CD45 move toward the periphery of the synapse and, by doing this, do not hinder the interaction. The synapse forms part of the events that favor the transcriptional activation of the TCR (Lee et al. 2002). The thinking behind this is that the TCR may contact the complexes several times in a cycle of binding/dissociation. Eventually, the TCRs are internalized and lost (Lanzavecchia et al. 1999).

The amounts of peptide–MHC complex that stimulate a T cell have been determined in some systems (Latek and Unanue 1999). They vary depending on the state of activation of the T cell. In unstimulated T cells the amounts are about 200–300 complexes per APC. This number is reduced greatly, to about 10 or even less, in already activated or 'memory' T cells. Note should be made of the high sensitivity of the immature thymocyte to MHC–peptide complexes. The estimates are that only two or three are needed for negative selection and killing of an immature thymocyte. Thus, central thymic recognition is highly susceptible to low numbers of complexes, as expected for a system that needs to eliminate self-reactive T cells.

The presentation of a peptide–MHC complex by an APC, and its engagement by a specific TCR, result in the activation of the T cell only under suitable conditions of cellular activation brought about by an inflammatory response. These conditions are those that lead to a change in the APC, in turn leading it to express a number of auxiliary molecules that foster the subsequent activation of the T cell. In situations where the number of peptide–MHC complexes is limiting and the APC is in a 'resting' state, the T cell will not respond or even undergoes a process of negative response called anergy (see Figure 1, p. 377).

The current thinking follows the 'two-signal hypothesis' (Bretscher and Cohn 1970): TCR engagement by itself is not sufficient to drive the T cell into proliferation and differentiation, and the additional participation of auxiliary molecules plays a role in what is a highly complex series of cellular events. Note that, in cell cultures, engagement of the TCR, say with an antibody, will not suffice to drive the T cell to proliferate unless a second antibody is added to one of the costimulator molecules (in this example to CD28). Engagement of the TCR without costimulation may result in anergy (Jenkins and Schwartz 1987).

Three sets of molecules foster the activation of a T cell on interaction with an APC: the membrane 'costimulator' molecules, which drive the T cell to enter the DNA cycle, activate some cytokine genes, and maintain their viability; adhesion molecules which serve to maintain the physical interaction of the two cells; and the cytokines which are released by the activated APCs and modulate the activation and differentiation of the T cell.

A number of cell surface molecules have been identified and are known to play an important role as costimulators (Linsley et al. 1990; Gross et al. 1990; Turka et al.

1990; Gimmi et al. 1991; Linsley and Ledbetter 1993; Sperling and Bluestone 1996). The CD28 molecule, a homodimer with a single immunoglobulin-like domain, is expressed on the T cell in small amounts, but increases during the activation process (Sharpe and Freeman 2002). The complementary ligand of CD28 is made up of two molecules on the APC, termed B7-1 (CD80) and B7-2 (CD86). Both are expressed in small amounts, but markedly increase their expression if the APCs are activated. Engagement of CD28 fosters T cell–APC adhesion, and increases the transcription of a number of cytokine genes, by activating a number of intracellular transcription systems including the Lck and itk molecules and the Jun and NF-κB pathways. Engagement of CD28 also increases the survival of the T cell through the expression of antiapoptotic molecules (such as BCl-xL). The end-result is a stronger response of the T cell in terms of both its growth survival and its production of cytokines such as IL-2. Mice with created mutations of the CD28 or B7 molecules respond poorly to antigen molecules.

Expression of the B7 family is fostered by activation of the APCs, by cytokines, particularly by TNF, and importantly by interaction with microbes and their products through the TLR molecules that activate the NF-κB pathways of transcription. B7-1 and B7-2 are also induced as a result of interactions involving another critical pair of surface molecules, the CD40 molecule expressed on B cells, DCs, and monocytes (Grewal and Flavell 1998). CD40 has structural homology to the TNF receptor family. Its complementary molecule is a member of the TNF family, the CD40-ligand molecule expressed on T cells in small amounts. Engagement of CD40 on DCs leads to a heightened expression of B7-1 and B7-2. Engagement of CD40 on the B cells is a critical step, because it results in their proliferation and differentiation to antibody-secreting cells. (The importance of the CD40–CD40-ligand molecules can best be found in children with mutations in the gene for the CD40-ligand, called 'hyper-IgM syndrome': its T cells are poor in providing helper activity, which clinically translates into problems in antibody formation against infections with a number of microbes.)

Other surface molecules are involved in fostering the APC interaction with T cells. In humans, the CD2 molecules on T cells also play a critical role akin to CD28. Also participating in the interaction are molecules that foster the adherence of the various cells. Among the adhesion molecules, the intercellular adhesion molecule 1 (ICAM) molecule in APCs is particularly important, fostering the contact with the α_2-β_1-integrins of T cells.

Soluble molecules also influence the outcome of the T cell–APC interaction. Cytokines produced by the APC influence the program of gene expression on T cells in important ways (Hsieh et al. 1993). Among the cytokines that are released on interaction of APCs with microbes, particularly bacterial products, are TNF, IL-1, IL-12, and IL-18. The last two influence the expression of interferon-γ by the CD4 T cell, a program of differentiation called 'Th1' (which contrasts with situations in which the cytokine Il-4 drives the expression of IL-4) (reviewed in Farrar et al. 2002; Murphy and Reiner 2002).

Finally, it is critical to stop the APC–T-cell interaction and regulate the extent of activation of the T cell. The interaction ends, of course, as the stimulus, the antigen molecules, becomes progressively more limiting and finally disappears. Also controlling the interaction are negative regulatory molecules. The molecule CTLA-4 is expressed briefly in the activated T cell. Its engagement by the B-7 molecules on APCs dampens T-cell activation. (Mouse strains with an absence of functional CTLA-4 show marked hyperproliferation of lymphocytes (Thompson and Allison 1997).) Cytokines also dampen the activity of APCs, and this most prominently includes IL-10 and transforming growth factor β.

INTRODUCTION

CD4$^+$ T cells are the conductors of the immunological orchestra, being not only responsible for many important effector functions, but also necessary for the activation of many other aspects of the immune response, including B lymphocytes, CD8$^+$ T lymphocytes, macrophages, and other inflammatory cells (Figure 1) (Boes and Ploegh 2004). Thus, there are few immune responses that do not involve CD4$^+$ T cells at some stage, a role that is underlined by the life-threatening susceptibility to infection seen in patients with a deficiency of this population in, for example, human immunodeficiency virus (HIV) infection.

NATURE AND ROLE OF CD4$^+$ T LYMPHOCYTES

CD4$^+$ T cells account for 60–70 percent of the T lymphocytes found in the bloodstream and in most organized lymphoid organs, including the spleen and lymph nodes, as well as the lymphoid tissues associated with the mucosal surfaces such as the Peyer's patches, appendix, and tonsils. Mature CD4$^+$ T cells are characterized by the expression of CD3, an αβ T-cell receptor (TCR) and the CD4 molecule, a four-domain monomeric member of the immunoglobulin (Ig) superfamily that binds major histocompatibility complex class II (MHC II). CD4 is also the primary receptor for HIV entry, binding the gp120 surface protein. Most resting CD4$^+$ T cells also express other pan-T-cell markers such as CD2, CD5, and CD28, many of which are important during the process of activation (see below). Unlike immature T cells in the thymus, mature CD4$^+$ T cells cannot express the CD8 molecule.

By virtue of the presence of CD4, the vast majority of this population recognizes peptide antigen when presented by MHC II molecules on the surface of an accessory cell, although there is an unusual subset of 'natural' CD4$^+$ T cells that accounts for less than 5 percent of the population and which recognizes nonclassic major histocompatibility complex (MHC) molecules such as CD1 (see below). Only a few cell types can be involved in the activation of CD4$^+$ T cells by foreign antigen – dendritic cells (DC), B lymphocytes, and activated macrophages. During inflammation,

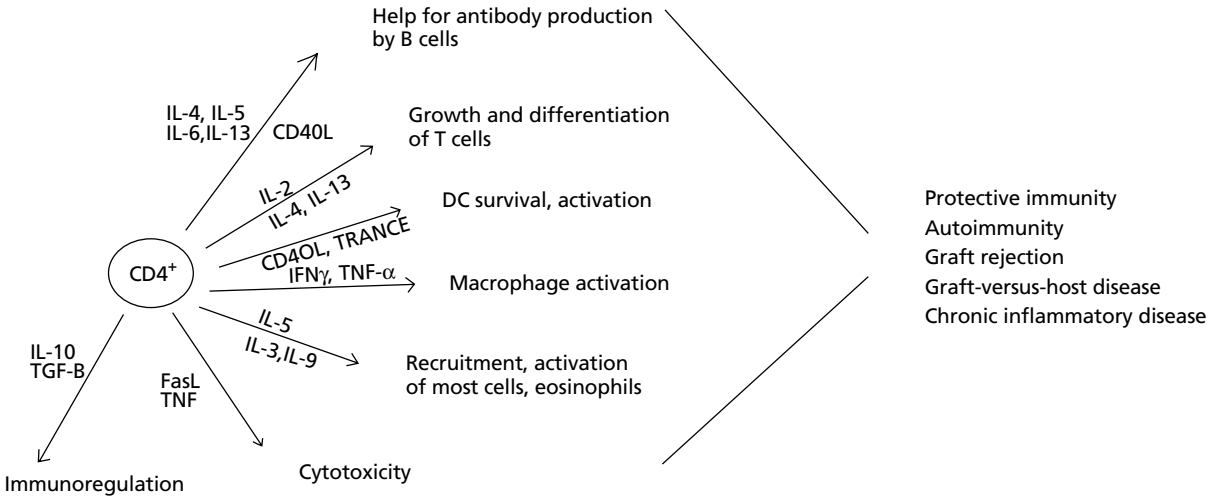

Figure 1 *Functions and roles of CD4+ T lymphocytes in protective immunity and immunopathology. DC, dendritic cell; IFN, interferon; IL, interleukin; TGF, transforming growth factor; TNF, tumor necrosis factor.*

other cell types can be induced to express MHC II, but the role of these cells in presenting antigen to CD4+ T cells in vivo is unclear.

As discussed elsewhere in this volume, antigens that are presented on MHC II molecules are derived from proteolytic processing mechanisms that generate 12–24 amino acid peptides within the endocytic pathway of the antigen-presenting cell (APC). As a result, CD4+ T cells are geared to recognize antigens that are taken up into APCs by phagocytosis, endocytosis, or pinocytosis. Thus, CD4+ T cells are important in protective immunity against extracellular pathogens such as pyogenic bacteria, large parasites, and other free-living organisms. In addition, intracellular pathogens such as *Mycobacterium*, *Salmonella*, and *Leishmania* spp., which survive in and colonize endosomes or phagosomes, can be recognized by CD4+ T cells (Boes and Ploegh 2004). Indeed, it is this group of infections that causes the biggest problem in CD4 deficiency states. Nevertheless, it is important to note that CD4+ T cells also play a prominent and often essential role in responses to other types of intracellular pathogens, which do not invade endosomes and characteristically stimulate MHC I-restricted T-cell responses (e.g. viruses). This may be secondary to the uptake of infected and/or damaged cells by phagocytic cells such as DCs or macrophages, or to the recycling of surface-expressed viral proteins via the endocytic pathway.

CD4+ T cells also play critical roles in most immune responses of pathological importance, including organ-specific autoimmune disease, chronic inflammatory disease, and other hypersensitivity disorders. In addition, alone or together with other lymphocytes, CD4+ T cells are important in the rejection of allogeneic transplants and in graft-versus-host disease after bone marrow transplantation (Figure 1).

LIFE HISTORY OF CD4+ T LYMPHOCYTES

Similar to all peripheral αβ T cells, CD4+ T cells differentiate from common lymphoid progenitor cells in the thymus, mostly during fetal and early postnatal life (Figure 2). The thymic processes of negative and positive selection ensure that the only CD4+ T cells that survive and are exported to the periphery have a TCR that can recognize foreign antigens when presented by self MHC II antigens, but cannot recognize self-tissue antigens (reviewed in Goldrath and Bevan 1999; Starr et al. 2003; Mathis and Benoist 2004). Positive selection occurs because maturing T cells are programmed to die by apoptosis unless they receive a signal from their TCR after it has interacted with self-peptides presented by self-MHC molecules, probably on the network of epithelial cells present in the thymic cortex. In turn, if the TCR has a very high affinity for self-MHC and peptide presented by thymic DCs, the cell will undergo negative selection ('deletion'), again by the induction of apoptosis. The exact timing of these events and their precise anatomical location are still somewhat controversial, but both selection processes occur soon after the T cell has acquired a CD3–TCR complex and when it still expresses both CD4 and CD8 markers ('double positives'). Thereafter, one of these markers is lost permanently as a result of silencing of the appropriate promoter; T cells with a TCR that recognizes peptides on MHC II molecules lose CD8 and retain the CD4 molecule; conversely, T cells with a TCR that recognizes peptides on MHC I molecules lose CD4 and retain CD8 (Figure 2). After commitment to the CD4 lineage, the single positive T cells enter the thymic medulla, where they spend a further period of 5–6 days, before emigrating to the thymus-dependent

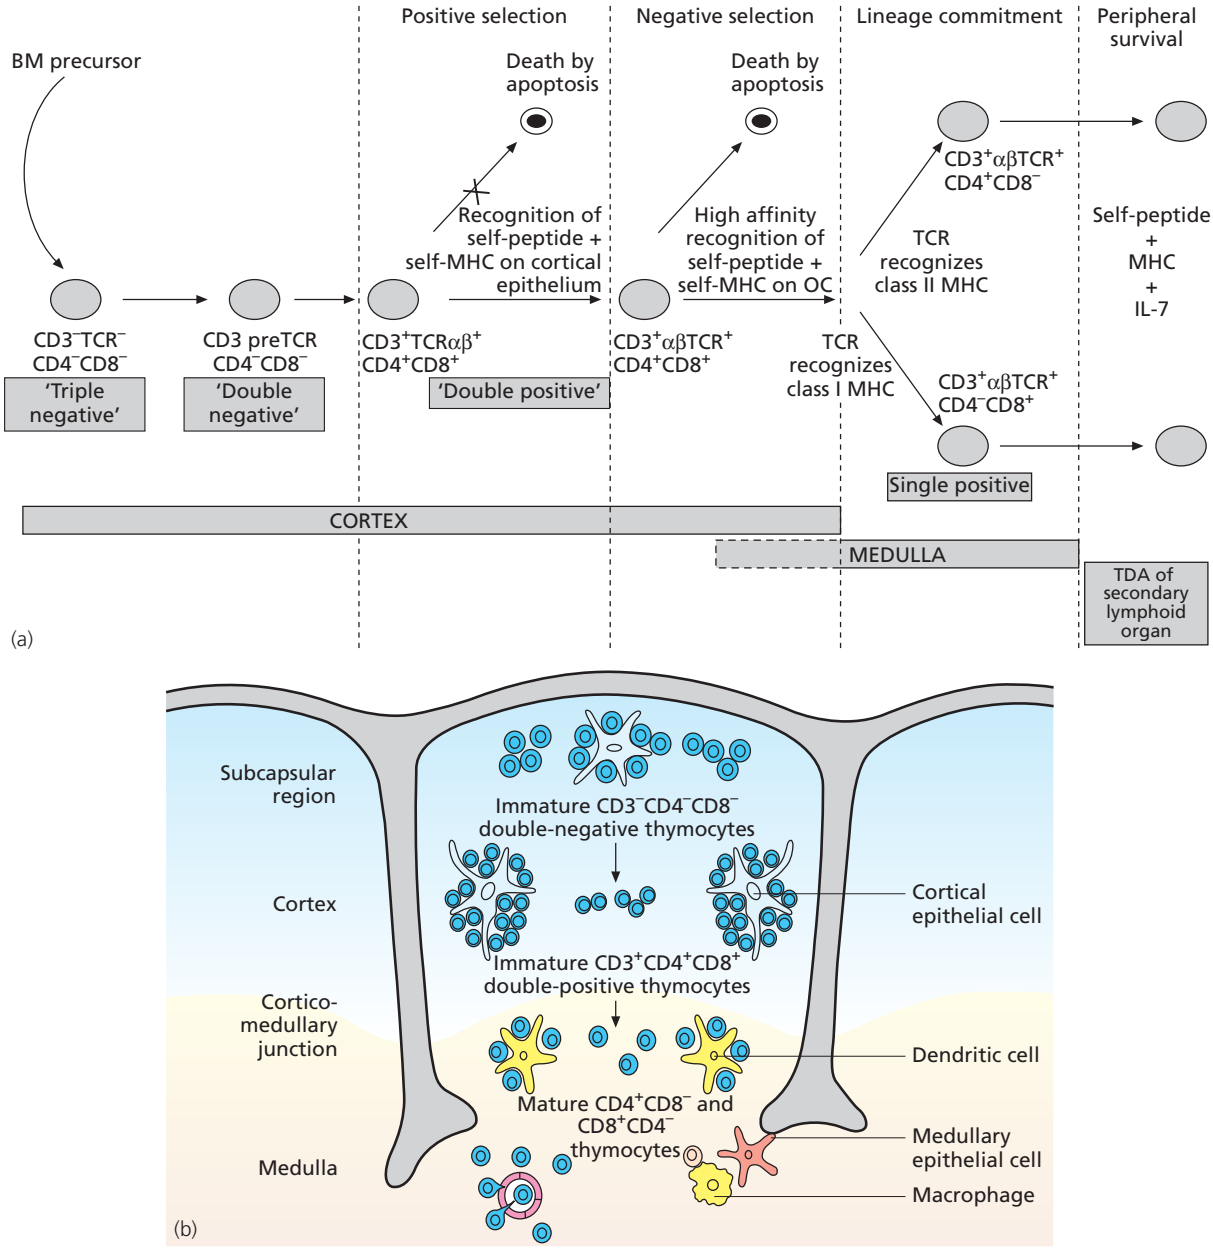

Figure 2 *Selection and differentiation pathways of T lymphocytes. Lymphoid precursor cells derived from the bone marrow enter the thymic cortex during fetal life and are induced to begin expansion and differentiation under the influence of soluble mediators and cell-surface molecules expressed by cortical epithelial cells and mesenchymal cells. At this time, the cells do not express a T-cell receptor (TCR), CD3, or CD4 and CD8 ('triple negative'), but they then rapidly acquire a pre-TCR composed of a TCR β chain and the pre-Tα chain, together with low levels of CD3 ('double negative'). Successful expression of this pre-TCR induces expression of both CD4 and CD8, and the mature αβ TCR replaces the pre-TCR. These 'double-positive' cells are now subjected to positive and negative selection, in which only those T cells expressing a TCR capable of recognizing self-peptides + self-MHC on cortical epithelium (positive selection), but which cannot recognize self-peptides + self-MHC strongly on dendritic cells (negative selection), are allowed to survive. This small fraction of cells (2–3 percent of total output) is then restricted to recognizing peptides from foreign antigens that are in complex with self-MHC molecules, but cannot recognize self-antigens with sufficient strength to cause autoimmunity. These selection processes probably occur mainly in the thymic cortex* **(b)**, *although the medulla may also play a role. After selection, T cells with a TCR that recognizes MHC I down-regulate the CD4 molecule and retain CD8 expression, whereas T cells with a TCR that recognizes MHC II down-regulate the CD8 molecule and retain CD4 expression. The resulting single positive T cells now remain in the medulla for a short period of further maturation, before exiting the thymus to recirculate from blood to the thymus-dependent areas (TDA) of secondary lymphoid organs. There they are maintained alive by continual low-level stimulation of their TCR ('tickling') by self-peptide + self-MHC on antigen-presenting cells in the tissues and by the cytokine interleukin 7 (IL-7). The insets show the histological appearance of the normal thymus, illustrating the cortex (C) and medulla (M), and a schematic representation of the local differentiation events. (From Janeway et al. 2001.)*

areas (TDA) of secondary lymphoid organs via the bloodstream.

At this time, the CD4+ T cells are referred to as 'naive', because they have not yet encountered antigen; naive T cells are in a resting state and can survive in this way for many years without stimulation by foreign antigen, or without constant output from the thymus. It was previously believed that outside stimuli were not required for this long-term persistence and that it was an inherent property of naive T cells. However, it is now clear that such T cells require continual stimulation via their TCRs to survive in the periphery (Goldrath and Bevan 1999). This does not involve foreign antigen, but seems to require recognition of the same self-peptide–MHC II complex that was responsible for positively selecting the T cell in the thymus. It is believed that DCs in secondary lymphoid organs are responsible for presenting these complexes and other factors, including cytokines such as interleukin (IL) 7 may also be involved (Figure 2) (Marrack and Kappler 2004; Stockinger et al. 2004). As a result of this 'tickling' by self-antigen under physiological conditions, the T cell does not usually undergo clonal expansion or become fully activated; instead it receives survival signals that allow it to persist in the peripheral tissues in a resting state. Interestingly, however, if the same CD4+ T cells are in an immunocompromised host, they can proliferate extensively under the influence of the same signals in an attempt to fill up the space in the 'empty' immune system. This has led to the concept that the normal immune system is tightly regulated to maintain a pre-set number of T cells and that this is determined by competition for a finite amount of MHC–peptide ligands and other survival signals. The phenomenon of 'homeostatic proliferation' is also important in understanding how the immune system may compensate for insults such as irradiation, chemotherapy, or HIV infection especially in adults, where the thymus is almost inactive.

ACTIVATION OF CD4+ T LYMPHOCYTES

Inappropriate CD4+ T cell activation can have serious consequences for the body because of the effects that these cells can have on surrounding tissues via the production of cytokines and activation of nonspecific effector cells. For these reasons, the activation of naive CD4+ T cells is subject to a number of stringent controls, including restrictions in the type and location of cells that can present antigen with MHC II, as well as a requirement for a sequence of highly defined signals to occur before full stimulation of the T cell is achieved (Boes and Ploegh 2004). For a complex antigen to be recognized by CD4+ T cells, it must be internalized by an appropriate APC, degraded into peptides in an endosomal compartment, and loaded on to newly synthesized class II MHC molecules, which are then expressed on the surface of the APC. In addition, the APC must express a number of nonpolymorphic accessory molecules that trigger specific receptors on the T cell and provide 'co-stimulation' of the signal obtained via the TCR (Sharpe and Freeman 2002) (Figure 3).

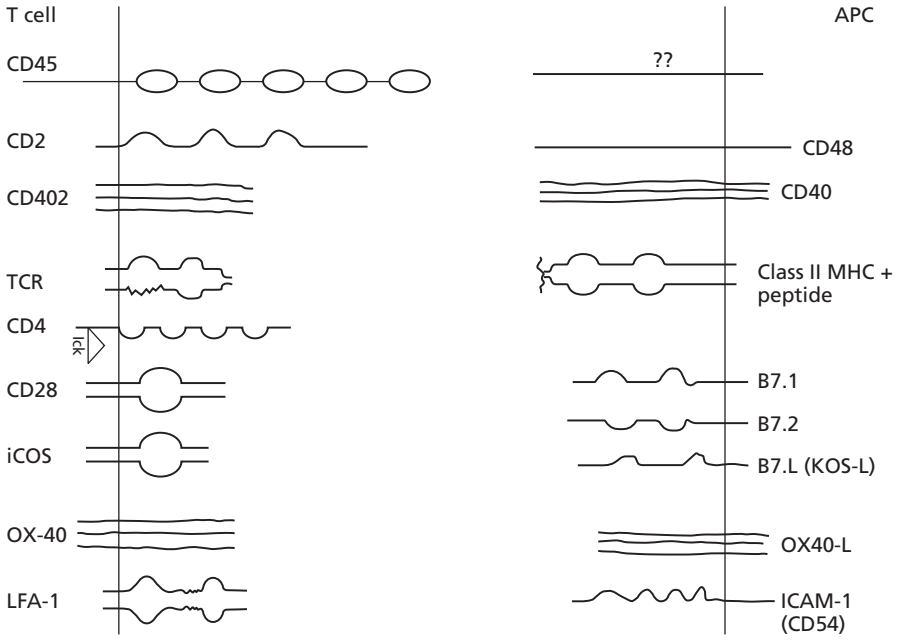

Figure 3 *Co-stimulatory molecules involved in T cell–antigen-presenting cell (APC) interactions and in the formation of the immunological synapse. ICAM, intercellular adhesion molecule; iCOS, inducible co-stimulatory molecule; MHC, major histocompatibility complex; TCR, T-cell receptor. See text for details.*

DENDRITIC CELLS AND PRIMING OF CD4+ T LYMPHOCYTES

In most immune responses, priming of CD4+ T cells occurs in the thymus-dependent areas (TDA) of secondary lymphoid tissues and the APCs are DCs. DCs are a specialized group of MHC II expressing leukocytes, which can be found in most tissues of the body, but they are most prominent in secondary lymphoid organs. There may be a number of different DC subsets and their exact functions may vary with their anatomical location, but their overall properties make them ideal candidates for initiating and directing CD4+ T-cell responses. They have several distinct, but related, roles (Banchereau et al. 2000; Guermonprez et al. 2002; Steinman et al. 2003). First, they are extremely effective at taking up and processing complex antigens for MHC II-restricted presentation. In addition, they are unique among APCs in their ability to patrol the tissues and solid organs of the body, before carrying antigen to the TDA of lymphoid organs where they meet naive T cells (Itano et al. 2003; Boes and Ploegh 2004). DCs are also capable of expressing a wide range of co-stimulatory molecules and can secrete soluble mediators that help in the activation and differentiation of T cells. Finally, and perhaps most importantly, all these DC functions are exquisitely sensitive to modulation by environmental signals derived from pathogens and damaged tissues, allowing DCs to act as the critical cell in linking innate and adaptive immunity. Essentially, they recognize threats to the body ('danger') and translate them into inflammatory signals that, together with specific antigen, the immune system can respond to in an appropriate manner (Banchereau et al. 2000).

The life history and functions of DCs have been elucidated in recent years, using a combination of in vivo and in vitro approaches (Figure 4). The tissue-resident DC is typified by the Langerhans' cell (LC) found in the epidermis of the skin, but analogous cells can be found in other epithelial surfaces and in solid organs. These cells are relatively immature, quiescent cells that are derived from a common myeloid precursor circulating in blood, the role of which is to continually sample the local environment. This reflects an extremely high and constitutive ability to take up exogenous materials by a variety of different mechanisms, including endocytosis, phagocytosis, and macrophagocytosis. However, at this stage, LCs and equivalent DCs are not effective APCs. Although they express MHC II, most of this is retained intracellularly within vesicular compartments and the small amount that reaches the cell surface is recycled rapidly. DCs remain in this quiescent state until exposed to products of pathogens or other inflammatory stimuli (Table 1). These include bacterial cell wall components such as flagellin, lipopolysaccharide (LPS), and other glycolipids, as well as bacterial DNA, viral nucleic acids, heat shock proteins, and a variety of cytokines released by infected or damaged cells, including IL-1, IL-6, and tumor necrosis factor (TNF) α. By binding to appropriate Toll-like receptors (TLR) (Barton and Medzhitov 2002) or cytokine receptors, these so-called 'danger signals' alert the DCs to the presence of potential harm and stimulate a number of coordinated, activation-related events in the DCs (Banchereau et al. 2000). Endosomal pH levels fall and acidic endosomal protease activity is increased, leading to increased availability of antigenic peptides as a result of enhanced processing of ingested antigen. Stable peptide–MHC II complexes are then exported to the cell surface and remain there for considerable periods of time (48 h or more). In parallel, the endocytic activities of the DCs fall dramatically, meaning that the cell focuses its MHC II processing and presentation activities on the antigen(s) that have provoked the threat of danger. At the same time as these changes in intracellular function, the DCs become motile and alter their expression of chemokine receptors, so that they leave the tissue via afferent lymphatic vessels and migrate to the draining lymph node. The most important chemokine receptor involved in these processes is CCR7, which binds the chemokines CCL (ELC) and CCL (SLC), which are produced in the TDA of lymphoid organs, and are responsible for recruiting

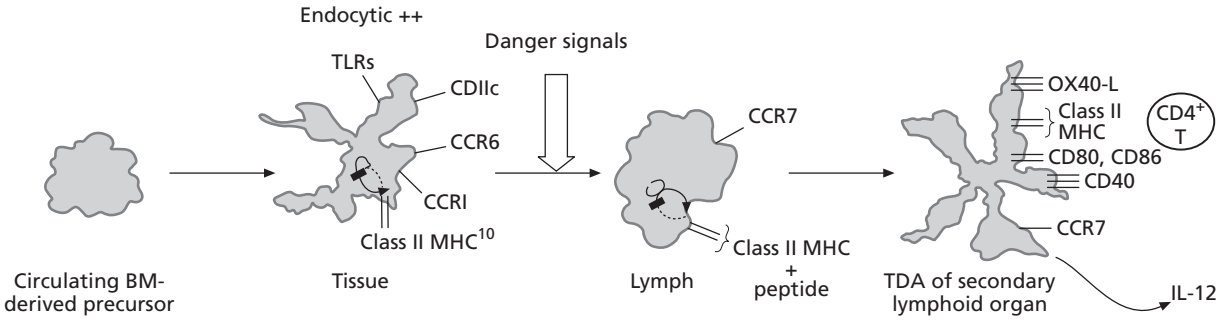

Figure 4 *Life history of dendritic cells (DCs). DCs derived from circulating bone marrow-derived precursors (myeloid or lymphoid) enter tissues in a relatively immature state; stimulation by pathogen-derived factors or inflammatory mediators then induces them to mature and emigrate from the tissue to the thymus-dependent area (TDA) of draining lymphoid organs via the afferent lymphatics. BM, bone marrow; IL, interleukin; MHC, major histocompatibility complex; TLR, Toll-like receptor. See text for details.*

Table 1 *Danger signals for dendritic cells*[a]

	Receptor
Pathogen associated molecule	
Bacterial lipopeptide	TLR-1
Bacterial lipopolysaccharide	TLR-2, TLR-4, CD14
Double-stranded RNA	TLR-3
Flagellin	TLR-5
Peptidoglycan	TLR-6
Bacterial DNA	TLR-9
Endogenous molecule	
Heat shock proteins	CD91
TNF-α	Type 1 TNF receptor (p55)
IL-1	IL-1 receptor
Histamine	H_1 histamine receptor

IL, interleukin; TNF, tumor necrosis factor.
a) These may be pathogen-associated molecular patterns (PAMPS) that normally interact with members of the Toll-like receptor (TLR) family, or endogenous mediators released during tissue.

both DCs and naive CD4+ T cells to this site (Randolph 2001). Quiescent DCs in tissues do not express CCR7, but have receptors for chemokines produced by tissue cells such as keratinocytes and intestinal epithelial cells (CCR6), as well as for chemokines produced during inflammation (CCR1, CCR2, CCR5). After activation, the expression of these receptors is inhibited, partly because activated DCs produce inflammatory chemokines that induce downregulation of their own receptors; in parallel, CCR7 expression is induced. As a result, the activated DC loses its ability to localize in tissues or inflamed sites and acquires the ability to migrate specifically to the TDA of lymph nodes (Figure 4).

The other important effect of DC activation is to induce the expression of the co-stimulatory molecules required for full activation of T lymphocytes, including CD80 (B7.1), CD86 (B7.2), and CD40. In addition, they become capable of producing immunomodulatory cytokines such as IL-12 (Figure 4). Together with all the other changes discussed above, the result is that DCs arriving in the TDA of lymphoid organs are now fully competent to activate and polarize effector T-cell responses. In return, the DCs receive signals from the T cell that promote DC survival and activate them further, much of which is mediated by CD40 ligand, which is in turn upregulated on the activated T cell (Banchereau et al. 2000).

DCs are not a homogeneous population and a number of different subsets have been described on the basis of origin, tissue distribution, differentiation status, and function (Banchereau et al. 2000; Guermonprez et al. 2002). In many species, it appears that DCs may develop from either myeloid or lymphoid precursors and in humans these are referred to as 'monocyte-derived' and 'plasmacytoid' DCs. The exact relationship between the subsets is not yet clear, but their potential importance is that different populations of DCs may have distinct effects on CD4+ T cells, selectively stimulating T-helper (Th) 1 or Th2 responses, or even T-cell tolerance. In addition, they may localize preferentially in different tissues.

OTHER TYPES OF ANTIGEN-PRESENTING CELL

It is now considered that DCs are the principal, if not the only, APCs capable of priming CD4+ T cells in vivo. However, other MHC II-expressing cells can act as APCs under some circumstances, especially in the later stages of primary immune responses or in secondary responses. Although macrophages normally degrade materials to the amino acid level, macrophages activated by microbial stimuli and/or interferon (IFN)-γ express high levels of MHC II and co-stimulatory molecules. Such macrophages may be able to sustain ongoing CD4+ T-cell responses, or even initiate them. B lymphocytes possess many of the features of APCs, including the constitutive expression of MHC II, the ability to process proteins in the endocytic pathway, and the expression of co-stimulatory molecules. In practice, the resting B lymphocytes found in normal lymphoid tissues cannot prime naive CD4+ T cells, but, as the response matures, direct presentation of antigen by activated B cells in germinal centers is essential for previously primed CD4+ T cells to help the differentiation of antibody-producing B lymphocytes. This presentation reflects the very high efficiency of antigen-specific B cells in internalizing and processing their cognate antigen via surface Ig. As the frequency of antigen-specific B cells is increased after primary immunization, these cells may also contribute to the initiation of secondary immune responses by presentation to CD4+ T cells.

Many tissue cells can express MHC II during inflammation, probably under the influence of IFNγ. This is exemplified by epithelial cells in the intestine, stomach, kidney, and thyroid during chronic inflammation, as well as by the β cells of the pancreatic islets in type 1 diabetes and by vascular endothelial cells in many different organs. The role of these cells in T-cell-mediated immune responses is controversial, because they usually do not express co-stimulatory molecules. Nevertheless, previously activated CD4+ T cells do not require as much co-stimulation as naive T cells and therefore MHC II-expressing tissue cells may sustain ongoing inflammation or protective immunity. Alternately, some workers believe that presentation of antigen by such APCs represents an attempt to downregulate the immune response by inactivating CD4+ T cells (see below) (Schwartz 2003).

SUPERANTIGENS

A specialized group of proteins can activate CD4+ T cells in an MHC II-restricted fashion, without the need for processing or co-stimulation. These are the 'superantigens', which act by forming a direct connection

between nonpolymorphic regions on the MHC II molecule and certain families of TCR (Sundberg et al. 2002). Both $CD4^+$ and $CD8^+$ T cells can be activated in this way, but most superantigens act predominantly on $CD4^+$ T cells. Most are also microbial products and they are capable of activating up to 25 percent of all T cells because of their ability to bind to framework regions on the TCR distant from the MHC–peptide-binding site. Although their recognition by T cells does not require proteolytic processing, superantigens must be presented with appropriate MHC molecules on the surface of APCs, in the same way as conventional peptide antigens. Superantigens have proved extremely useful experimental tools for dissecting T-cell functions and tolerance, as the responding families of T cells can be readily identified using appropriate specific antibodies. In addition, they may contribute to the pathogenesis of the infections caused by the various organisms by virtue of their ability to activate large numbers of T cells, stimulating the production of large amounts of proinflammatory cytokines. The best example is TSST-A, which causes the toxic shock syndrome associated with vaginal infection by *Staphylococcus aureus* after chronic tampon retention, and the others may have analogous effects.

ACCESSORY MOLECULES AND $CD4^+$ T-CELL ACTIVATION

As we have noted, several nonpolymorphic molecules on $CD4^+$ T cells are essential for effective activation by appropriate peptide–MHC complexes (see Figure 3). This partly reflects the fact that the TCR itself does not undergo major conformational change after binding to antigen and also has very short cytoplasmic regions, meaning that it is incapable of initiating intracellular signaling on its own. In addition, each TCR–MHC–peptide interaction is of relatively low affinity and may be extremely transient. Thus, additional molecules are required both to stabilize the binding of the T cell to an APC carrying specific antigen and to assist the biochemical signaling pathways.

The CD3 complex that is physically linked to the TCR on all T cells is critical to T-cell signaling, but does not contribute to the interaction with the APC and its functions are considered in T cell receptors. CD4 itself is the most important of the other molecules involved in these functions. It is a single chain molecule of 55 kDa, comprising four Ig superfamily domains, the outermost of which binds to nonpolymorphic residues on the α_2 domain of the MHC II molecule, distant from the peptide-binding groove. It is likely that each CD4 molecule may bind two separate MHC II molecules, each of which may bind a specific TCR, thus leading to the formation of 'pseudo-dimers'.

The binding of CD4 has two major effects on the T cell. First, it stabilizes the binding between the T cell and the APC, effectively increasing the affinity of the TCR for MHC–peptide and reducing the off-rate of this interaction. The second critical function of CD4 is to initiate tyrosine kinase-mediated signaling via the TCR. CD4 associates with the lck tyrosine kinase in the cell membrane and, after binding to the same MHC II as that bound by the TCR, CD4 brings lck into contact with the CD3–TCR complex, allowing lck to phosphorylate and activate the CD3ζ chain. This is the first and critical step in TCR-mediated signaling (see T cell receptors) and an analogous function is served by CD8 binding to MHC I on $CD8^+$ T cells.

Many of the remaining nonpolymorphic co-stimulatory molecules belong to the CD28 or TNF/TNF receptor families (Sharpe and Freeman 2002; Croft 2003). CD28 is present on all mature $CD4^+$ T cells and is a homodimeric molecule; each of the chains of this molecule is a 44-kDa Ig superfamily molecule comprising a proximal Ig C-like domain and a distal Ig V-like domain. It binds to two related ligands present on professional APCs: B7.1 (CD80) and B7.2 (CD86). They are homologous to each other and to CD28. The B7 molecules appear to dimerize on the APCs, each unit binding a separate CD28 molecule, creating a zipper-like binding lattice that provides a highly stable and effective cell–cell interaction.

Co-ligation of CD28 after TCR–peptide–MHC binding is essential for most aspects of $CD4^+$ T-cell activation, including clonal expansion, effector T-cell differentiation, germinal center formation, and memory cell generation. The exact mechanisms of action of CD28 are still unclear, but it is a potent signaling molecule that can activate a number of intracellular pathways in the T cell, some of which are unique to CD28, including the activation of phosphatidylinositol-3-kinase. Together, these effects amplify and sustain signaling via the TCR pathway, leading to increased IL-2 production, prolongation in the lifespan of IL-2 mRNA, and improved $CD4^+$ T-cell survival, probably involving upregulation of anti-apoptotic molecules such as bcl_{XL} and of the telomerase enzyme that assists telomere repair in dividing cells. In the absence of these CD28-mediated effects, productive T-cell activation does not occur and $CD4^+$ T cells are effectively blinded to the antigen.

A molecule related to CD28, which plays somewhat similar roles at a different stage of the immune response, is the inducible co-stimulatory molecule (iCOS). It is highly homologous to CD28, but is expressed only after CD28-mediated activation of $CD4^+$ T cells and binds to a B7-related ligand (B7RP1) on B lymphocytes. The primary function of iCOS appears to be in promoting the differentiation of effector T cells after initial clonal expansion has occurred and it co-stimulates the production of cytokines such as IFNγ, IL-4, IL-5 and IL-10, but not IL-2. It is also important in determining the outcome of T-cell–B-cell cooperation and in germinal center formation.

CD40 ligand (CD40L) is the most critical of the TNF-related molecules involved in $CD4^+$ T-cell activation. A homotrimeric molecule expressed on activated $CD4^+$ T cells, it binds CD40 on DCs and B cells, and is required for T-cell help of B-cell differentiation (see below), as well as for the production of IL-12 and differentiation of IFNγ-producing Th1 cells in most immune responses. Its expression on $CD4^+$ T cells requires activation via TCR and CD28, and ligation of CD40 on DCs or macrophages stimulates the expression of B7 molecules and the production of IL-12. Thus, CD40L plays an essential role in positive feedback stimulation of $CD4^+$ T cells and APCs, as well as in delivery of effector T-cell function. Mice lacking CD40L have a severe deficiency in IL-12 production and Th1-mediated defenses against intracellular pathogens.

Other related molecules involved in the co-stimulation of $CD4^+$ T cells include OX40, 4-1BBL, and TRANCE, which bind the DC molecules OX40L, 4-BB, and RANK respectively. The specific functions of these molecules are still under investigation, but they may overlap or synergize with those of the CD40L–CD40 interaction. In addition, ligation of RANK by TRANCE appears to play a unique role as a survival signal for DCs after interaction with antigen-specific T cells.

A number of adhesion molecules act as accessory factors during $CD4^+$ T cell–APC interactions, particularly in the initial, antigen-independent stage before specific TCR–peptide–MHC binding. These include intercellular adhesion molecule (ICAM)-3, and its interaction with its ligand DC-SIGN may be the first event in the binding of T cells to DCs. Leukocyte function antigen 1 (LFA-1) and its ligand ICAM-1 (CD54) are expressed on both T cells and APCs, and they play an essential role in forming the highly organized binding complex (the 'immunological synapse') that is responsible for focusing the TCR on relevant MHC II–peptide complexes (see Processing and presentation of antigen by the Class II histocompatibility system). Other accessory molecules include CD2, which is expressed on all T cells and binds to ICAM-3 and CD48 on APCs. As well as acting as adhesion molecules, ligation of all these receptors can also enhance signaling within the T cell.

TOLERANCE AND IMMUNITY AS ALTERNATIVE OUTCOMES OF $CD4^+$ T-CELL ENCOUNTER WITH ANTIGEN

Productive activation of $CD4^+$ T cells is not the only possible consequence of presentation of MHC II–peptide complexes and, under some circumstances, the T cell may be inactivated, leading to the phenomenon of specific immunological tolerance. In this situation, the T cell not only fails to make an effective primary response to antigen, but is also unresponsive to subsequent re-stimulation with the same antigen, even if it is presented under conditions that would normally induce a strong immune response. Tolerance is critical for preventing immune responses to tissue antigens by self-reactive $CD4^+$ T cells that have escaped deletion in the thymus. It is also useful for preventing inappropriate responses to harmless foreign antigens, particularly when such responses could lead to tissue damage. Antigens of this kind include the fetus, food proteins, aerosol antigens, and commensal bacteria.

There are many theories and mechanisms to explain the induction of tolerance rather than productive immunity in $CD4^+$ T cells (Table 2). As all the antigens (self and foreign) that induce tolerance share the property of not stimulating inflammation and so not inducing the activation of APCs, it seems that tolerance develops when the antigen is presented by APCs that lack appropriate co-stimulatory molecules. Under these conditions, the $CD4^+$ T cell is partly activated after recognizing its specific peptide–MHC II complex on the APC, but does not receive the additional accessory stimuli necessary for full IL-2 production (Schwartz 2003). As a result, the T cell undergoes cell cycle arrest, probably mediated in part by accumulation of inhibitory factors within the cytoplasm, and it fails to make sufficient cell divisions to ensure an adequate primary response. In addition, the aberrant signaling in the T cell renders it unable to respond to subsequent stimulation via the TCR, permanently preventing effector cell differentiation. Despite these defects, these so-called 'anergic' T cells may also retain some functional capabilities, including the production of cytokines such as IL-10 and transforming growth factor (TGF) β, allowing them to inhibit the functions of other T cells and APCs. Such 'regulatory T cells' (T_{reg}) appear to play an important role in maintaining many forms of tolerance in vivo, because they can prevent the activation of naive, fully responsive $CD4^+$ T cells when antigen is next encountered (Maloy and Powrie 2001). A number of such T_{reg} cells have been described, of which the most studied recently is the $CD4^+CD25^+$ subset, which appears to be a naturally occurring regulatory cell derived from the thymus and which controls immune responses to self-antigens in peripheral tissues by as yet ill-defined mechanisms (Sakaguchi 2004). Others include the Tr1 cell, which differentiates in response to foreign antigen under the influence of environmental IL-10 and acts by producing IL-10 itself (Roncarolo et al. 2001).

Current evidence suggests that the APCs responsible for inducing tolerance in $CD4^+$ T cells may not be completely lacking in accessory molecules and that the process requires an alternate set of co-stimulatory events (Greenwald et al. 2002). Of these, the best understood is that involving CTLA-4, a homolog of CD28 that is expressed mainly on activated $CD4^+$ T cells, but which also can be involved in the earliest phase of T-cell interaction with APCs. Similar to CD28,

Table 2 *Potential mechanisms of tolerance*

Mechanisms	
Clonal deletion	Self-antigens in thymus
	Very high doses of peripheral antigens?
	Apoptosis after ligation of TCR
Clonal anergy	Self-antigens in thymus
	Self-antigens in periphery
	Harmless foreign antigens in periphery (foods, commensals, etc.)
	TCR ligation in absence of co-stimulation (or with dominant negative co-stimulation by, for example, CTLA-4) → partial activation, failure to transcribe IL-2 gene, defective clonal expansion, and no proliferation/IL-2 production on challenge
Regulatory T cells	T cells actively inhibit priming/functions of other, naive T cells
	Self-antigens in thymus – $CD4^+CD25^+$ T cells
	Self + foreign antigens in periphery
	$CD4^+CD25^+$ T cells generated by aberrant selection in thymus
	Regulatory T cells induced in periphery by resting APCs or APCs conditioned by, for example, IL-10
	$CD4^+CD25^+$ T cells act by cytokines, cell-cell contact
	Peripheral T_{reg} act by producing IL-10/TGF-β (Tr1, Th3)
Clonal ignorance	Antigen sequestered from T cell and not recognized by TCR
	Self-antigens such as lens protein, testis
	Specific T cells still present and potentially reactive

See text for details.
APC, antigen-presenting cell; IL, interleukin; TCR, T-cell receptor; TGF, transforming growth factor.

CTLA-4 binds CD80 and CD86 and was originally thought to have identical co-stimulatory functions. However, the observation that CTLA-4 knock-out mice developed fatal a lymphoproliferative disease led to the recognition that the principal role of CTLA-4 is to downregulate $CD4^+$ T-cell responses. The exact mechanisms responsible for this effect are not yet known, but it is clear that ligation of CTLA-4 transmits an inhibitory signal to the T cell and that this dominates over other, potentially stimulatory, signals. This can occur late in T-cell responses, when it is important to prevent over-activation of the immune response; this is probably the explanation for the high expression of CTLA-4 on activated T cells, when CD28 is also decreasing. In addition, CTLA-4 has higher affinity for CD80 and CD86 than CD28, meaning that CTLA-4 binding will predominate when the co-stimulatory molecules are expressed at low levels on APCs. As discussed, this is most likely to occur when APCs have not been activated adequately and it has been shown that the induction of tolerance in $CD4^+$ T cells requires early ligation of CTLA-4. Thus, CTLA-4 and CD28 play overlapping, but opposing, roles in the response of $CD4^+$ T cells to antigen, allowing the T cell to discriminate between dangerous antigen presented in the context of inflammation and self or harmless foreign antigens to which tolerance is necessary.

An additional co-stimulatory molecule on T cells that appears to play a preferential role in the induction of tolerance in $CD4^+$ T cells is PD-1, which is a CD28/CTLA-4 homolog that binds PDL-1 and PDL-2 on APCs. Its functions are not yet fully understood, but seem to involve activation of intracellular phosphatases that inactivate the tyrosine kinase signaling pathways of TCR-mediated activation.

DIFFERENTIATION AND FUNCTIONS OF TH1 AND TH2 CELLS

As noted above, $CD4^+$ Th cells are central to the normal immune response and are essential for protective immunity against a wide range of potentially pathogenic organisms. However, $CD4^+$ T cells can be further subdivided depending on the pattern of cytokines they produce and the type of immune response they support. The cardinal marker of Th1 T cells is the secretion of IFNγ. This cytokine is essential for the cell-mediated immune responses generally required for protection against intracellular pathogens such as *Leishmania* spp. and mycobacteria. In contrast, Th2 cells were defined by their production of IL-4 and a role in helping humoral immunity and responses against extracellular pathogens such as helminths (Abbas et al. 1996). Th1 and Th2 responses tend to be reciprocally regulated and their importance has been highlighted in a number of disease models where susceptibility or resistance to a particular pathogen is dependent on the ability to mount the appropriate Th1 versus Th2 response. Dysregulation of these responses may also be involved in a number of inflammatory disorders.

A number of models have been proposed to explain the process by which a naive precursor CD4+ T cell can become either a Th1 or a Th2 cell (Murphy and Reiner 2002; O'Garra and Robinson 2004). Distinct precursors may exist and must become either Th1 or Th2. Alternately, cells could switch between the Th1 and Th2 phenotype, but can express only one particular phenotype at a time. However, it appears from studies in a number of TCR transgenic systems, where cells of the same specificity can mount a Th1 or a Th2 response, depending on the priming conditions, that the most likely explanation is that a common precursor exists which can differentiate into either Th1 or Th2 (Figure 5).

A large body of work has shown that cytokines are centrally important in causing naive CD4+ T cells to differentiate into IL-4- or IFNγ-producing cells. Cytokines may exert their polarizing influence by acting directly on T cells or via APCs, and may have one or all of the following effects: promote differentiation of precursor Th cell towards a particular phenotype, cause preferential proliferation of a particular phenotype (i.e. expansion not differentiation), or inhibit either of the above for a particular subset, thereby leading to dominance of the other.

The heterodimeric cytokine IL-12 is a potent inducer of IFNγ production by both natural killer (NK) cells and T cells, and is the principal Th1-inducing cytokine. Many adjuvants and microbial products stimulate IL-12 production from macrophages and DCs and it interacts directly with naive Th cells. Indeed, functional receptors for IL-12 are present on recently activated, uncommitted cells and Th1 cells but are lost from differentiated Th2 cells. IL-18 is an IL-1-related cytokine that assists the IL-12-induced differentiation of Th1 cells, although it may also enhance Th2 responses under some conditions. Other cytokines that may be involved in Th1 cell development are IL-23 and IL-27, both of which are partly related to IL-12. IFNγ also plays a role in the development of Th1 and Th2, partly because it inhibits the clonal expansion of IL-4-producing Th2 cells and

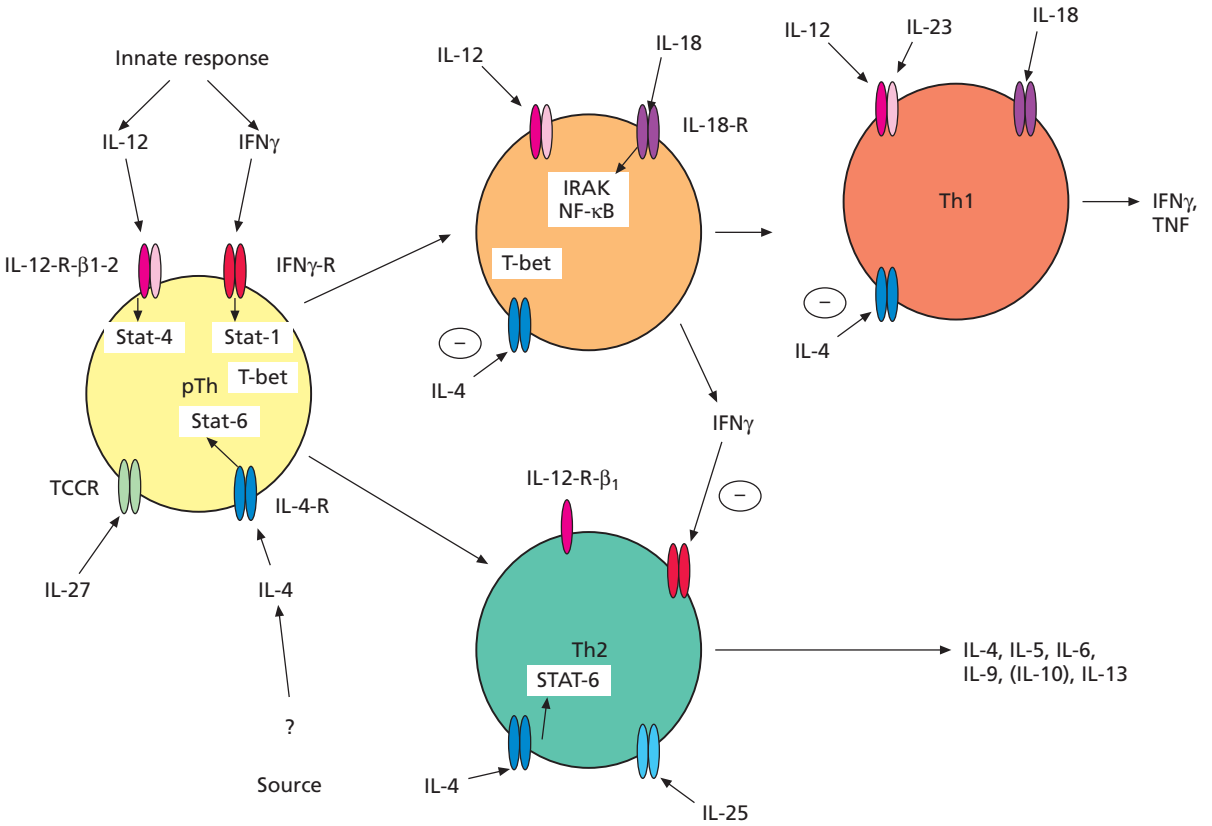

Figure 5 *Naive CD4+ T cells can differentiate into either T-helper 1 (Th1) or 2 (Th2) cells after recognition of antigen, depending on signals derived from the local microenvironment. Interleukin IL-12 released by macrophages and dendritic cells (DCs) in response to, for example, intracellular pathogens binds to the IL-12-R-β1/-2 receptor, triggering signaling through Stat-4 and the consequent production of interferon-γ (IFNγ) and activation of the T-bet transcription factor. This leads to increased expression of the IL-18-R, allowing IL-18 released from a wide variety of cell types (including potential APCs) to enhance the production of IFNγ and further differentiation to the Th1 lineage via activation of NF-κB. Th1 cells maintain expression of the IL-12-R-β1/-2 chains, allowing continued positive feedback via IL-12 and the synergistic effects of IL-23 derived from cells such as macrophages and DCs. Th2 differentiation is dependent on IL-4, but its source early in the response is unknown. IL-4 acts by activating transcription factors such as Stat-6 and GATA-3. Developing Th2 cells lose expression of the IL-12-R-β-2 chain making them unresponsive to IL-12/IL-23, but maintain expression of the IFNγ-R, which accounts for the inhibitory effect of IFNγ on Th2 cell differentiation.*

also because it enhances IL-12 production by APCs and maintains the expression of functional IL-12 receptors on $CD4^+$ T cells.

IL-4-producing Th2 cells emerge if IL-4 is present during priming, particularly if this is accompanied by the suppression of the appearance of IFNγ-producing cells. IL-4 appears to act directly on T cells and, once established, the IL-4-producing phenotype appears to be very stable. Another Th2 product, IL-10, diminishes IL-2 and IFNγ production by primed T cells, but, in contrast to IL-4, it appears that IL-10 acts via the APCs by suppressing production of the Th1-polarizing cytokine IL-12. Overall, it appears that IL-10 may contribute to the differentiation towards Th2 but it is not essential; this is supported by the fact that IL-10 knockout mice are capable of mounting Th2 responses.

WHAT ARE THE SOURCES OF THE CYTOKINES THAT POLARIZE TH1 AND TH2 RESPONSES IN VIVO?

Dendritic cells and to some extent macrophages are the sources of the IL-12 essential for the development of Th1 cells. However the in vivo source of IL-4 to promote differentiation into Th2 is more contentious. Naive T cells do not make appreciable amounts of IL-4 and differentiated Th2 cells would make a contribution only in an already primed animal. However, $NK1.1^+$ T cells, which recognize antigens presented in association with the nonpolymorphic β_2-microglobulin-associated molecule, CD1, can produce considerable amounts of IL-4 very rapidly on activation (Chen et al. 1997). However, the role of these cells remains controversial because Th2 responses can still be induced in the absence of these cells. Alternately, cells of the mast cell/basophil lineage may be the source of IL-4, possibly after triggering of the FcεRI or FcγRII/III receptors. Although this would require pre-existing IgE or IgG1 antibodies, mast cells and basophils can be activated nonspecifically by agents such as helminth products.

OTHER FACTORS IN CONTROL OF $CD4^+$ T-CELL DIFFERENTIATION

A number of factors have been implicated in the polarization of naive $CD4^+$ T cells into Th1 or Th2 cells, including the nature of the APC, the dose of antigen, and the co-stimulatory molecules involved (O'Garra and Robinson 2004).

Initial ideas suggested that DCs were responsible for polarizing Th1-cell responses, whereas presentation of antigen by B lymphocytes induced Th2-cell responses preferentially. However, it now appears that all APCs can initiate either form of T-cell response, although different populations of APCs may influence the subsequent maintenance of the distinct forms of response. This may reflect differential production of and/or response to polarizing cytokines, or via the expression of different co-stimulatory molecules (see below). Recently it has been proposed that the distinct lineages of DCs (lymphoid vs myeloid: DC1 vs DC2) may promote the selective differentiation of Th1 and Th2 respectively.

However, again it seems that this is an oversimplification and that all DC subsets may promote either Th1 or Th2 responses under appropriate circumstances. Recent studies indicate that DCs exposed to the cytokine thymic stromal lymphopoietin, produced by tissue cells from atopic individuals, induce Th2 differentiation, suggesting that this may be a corollary for IL-12 and Th1 differentiation in allergic disease (Soumelis et al. 2002). Indeed by altering the affinity of the peptide interaction with the class II molecule or the TCR it has been found that an overall lower affinity favors Th2 priming, whereas Th1 responses dominate if there is high affinity. These findings can be summarized as follows:

Co-stimulation

It has already been suggested that APCs may play a role in the differentiation of Th subsets and that they may do this via their expression of co-stimulatory molecules. Most work in this area has concentrated on the interaction of the well-known co-stimulatory molecules CD28 and CTLA-4 with their ligands B7-1 (CD80) and B7-2 (CD86). However, a variety of blocking or 'knock-out' studies in a wide range of experimental models in vitro and in vivo have yielded conflicting results (O'Garra and Robinson 2004). The confusion is probably related to the fact that, as noted above, the initial interaction of CD28 (or CTLA-4) with its B7 ligands is required for T-cell priming but it may then have differential effects in the expansion and persistence of Th1 and Th2 responses. The role of CTLA-4 in Th1/-2 polarization is also complicated by the negative regulatory effects of this molecule.

It has become apparent recently that a third signal may also be required to elicit co-stimulation for T cells and this may be mediated by iCOS, which is a homolog of CD28, and does not bind either B7-1 or B7-2 but rather interacts with B7-related protein 1 (B7RP-1). This ICOS is not present on naive T cells but is induced on all activated T cells. The signaling of iCOS appears to be involved the generation and maintenance of both Th1 and Th2 responses, but may be of heightened importance in the latter because iCOS expression is sustained on Th2 cells after chronic stimulation.

Thus, the overall affinity of the interaction resulting from the net effects of ligand density, affinity with APCs and TCR, and co-stimulation may be important in determining the type of response initiated but must be viewed in the context of the cytokine environment induced in vivo. It now seems likely that the convergence point for all of these influences is the signal transduction across the cell membrane and this is discussed in greater detail in T cell receptors.

Genetic background

A final, and relatively poorly defined, influence on Th polarization is that of non-MHC genes. Different inbred strains of mice have long been known to express distinct resistant or susceptible phenotypes to a variety of infections (e.g. *Leishmania major*, *Trichuris muris*) even when they are of the same MHC genotype, implying that genetic influences other than the MHC may be important. Studies using TCR transgenic animals backcrossed onto congenic strains that have the same MHC II antigens but different background genes have demonstrated that these genes influence naive T-cell polarization. The effect in this system appeared to be at the level of the T cell because mixing APCs and T cells from the different strains always led to the production of the cytokine profile associated with the T cell rather than the APC. Thus, it appears that T cells on a BALB/c background default to a Th2 phenotype as a result of greater initial IL-4 production and a decrease in IL-12 responsiveness resulting from the loss of IL-12-Rβ_2 expression. In contrast, animals on the congenic B10.D2 background do not display early IL-4 production and maintain IL-12-Rβ_2 expression and IL-12 responsiveness to develop a default Th1 phenotype.

PHENOTYPIC MARKERS OF TH1 AND TH2 CELLS

One of the major hindrances to progress in the study of Th1 and Th2 polarization has been the lack of reliable phenotypic markers of the two subsets. However, recent studies have identified several candidate molecules (Sallusto et al. 1998). The ligands for P- and E-selectin are preferentially expressed on Th1 cells and facilitate differential migration of these cells into inflammatory sites such as inflamed joints or sensitized skin (Austrup et al. 1997). The migration of Th2 cells, eosinophils, and basophils into tissues undergoing allergic reactions appears to be mediated by the eotaxin (a chemokine) receptor, CCR3, which is expressed on all of these cells but not Th1 cells (Sallusto et al. 1998). Another chemokine receptor, CCR5, may be restricted to Th1 cells whereas the IL-1-R homolog, ST2L, may occur only on differentiated Th2 cells.

B-CELL HELPER FUNCTION OF CD4+ T CELLS – THE GERMINAL CENTER REACTION

The antibody response is an essential component of the immunological armory. In many cases the development of antibody-producing plasma cells from B cells is highly dependent on help from T cells, as evidenced by the lack of B-cell responses in congenitally athymic animals that lack T cells. For an antibody response to occur, rare antigen-specific T and B cells must encounter the antigen that they both recognize and each other. This is achieved in germinal centers in the secondary lymphoid organs (MacLennan 1994).

As discussed above, following exposure to antigen it is transported to the secondary lymphoid tissues, either in blood/lymph or by specialized antigen-transporting cells (e.g. Langerhans' cells in skin). The activated, laden APC has now upregulated receptors (e.g. CCR7) for chemokines (e.g. CCL19, CCL21), which are produced by the stromal cells and other APCs in the thymus-dependent T cell area of the lymph node (paracortex), and is thus attracted to this area. Recirculating naive T cells also express CCR7 and therefore also localize in the paracortex, optimizing the chance of them encountering their cognate antigen (Sallusto et al. 2000). The naive T cell can now 'see' antigenic peptide presented to it in the context of MHC II by the antigen-laden APC. This results in upregulation of co-stimulatory molecules such as CD40L, the production of cytokines, and further migration. Naive B cells also recirculate but they express a chemokine receptor (CXCR5) that is specific for a chemokine (CXCL13). CXCL13 is preferentially produced by the network of follicular DCs that forms the basic structure underlying the B-cell areas of the lymph nodes or primary follicles. Within the specialized B-cell follicle, the naive B cell has also acquired antigen via its surface immunoglobulin (sIg) by this stage, which leads to its activation. It is important to note that although there are very few B cells of any particular antigen specificity they have an enhanced capacity to acquire specific antigen because of their surface receptor. The activated B cells now upregulate their expression of CCR7 and are drawn towards the T-cell area of the lymph node. Antigen-specific T and B cells now meet at the border between the paracortex (Garside et al. 1998) and the follicle, as a result of what has been termed 'a balanced responsiveness' to chemokines produced in each area. Thus, sampling and transport of foreign molecules from all over the body to secondary lymphoid 'depots' that are under constant surveillance by recirculating, naive lymphocytes has maximized the opportunity for these cells to encounter their specific antigen. Furthermore, coordinated expression of chemokines and their receptors has brought activated antigen-specific T and B cells into close proximity within the lymph node (Cyster 2003).

A range of membrane-associated and soluble molecules is now employed to help T and B lymphocytes 'talk' to each other in a variety of ways. Most of these 'conversations' take place within and around the developing germinal center (Cyster 2003). Germinal centers are the specialized anatomical microenvironment where activated B cells proliferate and attempt to increase the affinity of their antibody for the eliciting antigen in the process known as affinity maturation (MacLennan 1994).

Germinal centers are derived from the primary follicles, which, as noted above, are the sites to which naive recirculating B cells migrate as they pass through the lymphoid tissue. Primary follicles contain resting B cells clustered around a network of processes extending from follicular dendritic cells (FDC) (Cyster 2003). FDCs are important in attracting B cells to follicles, but also play an important role in affinity maturation by holding intact antigen and/or antigen–antibody complexes on their surfaces for long periods of time.

To make an antibody response a B cell needs to hypermutate, survive, proliferate (clonally expand), differentiate, and secrete antibody. T cells help B cells to do all of these things. B cells that have acquired antigen via their specific receptor (sIg) are now further activated by presenting peptides from that antigen on their surface and undergoing a cognate interaction with Th cells specific for the same antigen. The necessity for this cognate interaction is demonstrated by the facts that the correct antigen and restriction element (MHC II) are required to elicit T-cell help for B cells. This is important to prevent nonspecific bystander activation of B cells, which could lead to autoantibody production. These activated B cells within the primary lymphoid follicle now start dividing to form germinal centers, and these tightly packed, proliferating B lymphocytes, which no longer express sIg, are referred to as centroblasts, and form the dark zone of the germinal center (MacLennan 1994).

For affinity maturation to occur, variability is randomly generated in the B-cell receptors and those with the highest affinity are selected. Random point mutations are targeted to the V-region genes of the rapidly dividing centroblasts in the process of somatic hypermutation. Newly configured mutant receptors are now expressed as sIg on the progeny of the centroblasts, which are known as centrocytes. Centrocytes subsequently migrate towards the FDC network in the light zone of the germinal center where they can encounter Th cells that have also migrated there. Centrocytes die by apoptosis within a short time of expressing their new sIg unless it is bound by antigen; then they are contacted by an activated Th cell expressing the survival signal CD40 ligand (CD40L). The random process of somatic hypermutation also means that the sIg expressed on the centrocytes derived from a particular progenitor may bind and take up antigen more or less efficiently than that expressed on its precursor. Centrocytes with mutations that result in a loss of the ability to bind antigen die by apoptosis. However, if the mutant sIg binds antigen well, the centrocyte is induced to express the *bcl-xl* gene, the product of which inhibits apoptotic cell death, and the cell is rescued. It is in this competitive environment that centrocytes with the highest affinity receptors bind and take up antigen and move to the outer edge of the light zone, where activated Th cells expressing CD40L are concentrated, whereas those with low-affinity receptors lose out and die by apoptosis (Rathmell et al. 1996). If the centrocyte and Th cell are specific for epitopes from the same antigen, they undergo a cognate interaction during which they exchange signals that promote their further proliferation and differentiation. The B cells become either memory cells or antibody-secreting plasma cells and may have also undergone isotype switching in response to cytokines secreted by Th cells. The involvement of T cells in the selective process in the germinal center prevents survival of centrocytes that have acquired specificity for self-antigens.

EVOLUTIONARY CONTEXT: OVERVIEW OF THE ADAPTIVE CELLULAR IMMUNE SYSTEM

Many infectious agents are obligate intracellular parasites. All viruses meet this description, as do many pathogenic prokaryotes and unicellular eukaryotes. Cellular organisms can also be opportunistic intracellular interlopers, particularly if it enables them to escape the clutches of the humoral immune system. Cells are not wholly defenseless against intracellular microorganisms, although the capacity of such innate immune mechanisms is relatively limited.

An important part of the innate response of infected cells is the manufacture and release of cytokines (most commonly α- and β interferons). In many circumstances, this provides the initial warning of the invasion to the organism. At this juncture two strategies are conceivable: the immune system could indiscriminately target the general vicinity of the infected cell and implement an anti-pathogen program akin to carpet bombing. As immune effector mechanisms can have deleterious effects on cells (the ultimate being death, of course) this would come with a high cost in collateral damage. Alternately, the immune system can selectively target infected cells for individual attention. This is a sufficiently attractive possibility for vertebrate organisms to make an enormous evolutionary investment to achieve it.

The essential problem faced by the immune system is the efficient identification of infected cells in a spatially complex organ. Any reasonable solution entails endowing immune cells with the ability to detect the presence of intracellular pathogens without disrupting the integrity of cells harboring the agent. This was achieved by the evolution of a molecule that carries small bits of information encoded by the pathogen to the surface of the infected cell for perusal by immune cells bristling with receptors which co-evolved the capacity to decode the information. The information-carrying molecule is known as a major histocompatibility complex (MHC) class I molecule. The information takes the form of pathogen-encoded oligopeptides (usually 8–11 residues in length). These are generated by the antigen-processing machinery, which, like class I molecules, is constitutively expressed by virtually all cells in a vertebrate organism. Decoding is performed by a receptor (the αβ T-cell receptor (TCR) expressed by cells (the $CD8^+$ T cell) charged with the task of finding and modifying cells expressing nonself peptides.

This is an impressive achievement, but the system has a potential flaw: pathogens can evolve to mimic self-peptides and avoid detection. To discourage this, an additional level of complexity was added. The value added by this modification is best illustrated by its high cost. Alleles of MHC class I genes evolved that present distinct sets of peptides. Such alleles are present in the population of most vertebrate species at sufficient frequencies to make it likely that any two individuals present substantially different sets of peptides on their class I molecules. This is the inexpensive part.

As every American parent with college-age children painfully knows, life's real expense comes in education. Since the immune system in any individual cannot anticipate which class I molecules it must recognize, its TCRs cannot be hard-wired into the genome. Rather, evolution invented thymic selection to select, among T-cell clones

expressing different TCRs, for those that are capable of recognizing self class I molecules with the proper affinity.

The thymus is more akin to a mortuary than a kindergarten, because the vast majority of T cells entering cannot meet the exacting standard of expressing a TCR that binds to class I molecules with the intermediate affinity required to enable self–nonself discrimination. Given that humans can generate up to 10^9 T cells per day (at birth, the peak of thymic activity), which represents 2–5 percent of immature thymocytes entering the thymus, the daily carnage amounts to perhaps 2×10^{10} cells (50 g or so) (Haynes et al. 2000)! Waste is a theme that we return to when discussing the generation of antigenic peptides.

$CD8^+$ T cells are but half of a dynamic duo, their partners being $CD4^+$ T cells. The siblings are charged with largely distinct tasks. $CD8^+$ T cells serve as a principal immune effector mechanism for fighting viruses and other intracellular parasites. $CD4^+$ T cells are preoccupied with regulating the activities of other immune cells, including their $CD8^+$ T-cell siblings. $CD4^+$ T cells also recognize oligopeptides (occasionally the same peptides as $CD8^+$ T cells), but presented by MHC class II molecules (dead ringers for class I molecules structurally, but very different in primary sequence). $CD8^+$ and $CD4^+$ T cells acquire their TCRs from a single gene pool. The discrimination of class I versus class II molecules results from the expression of the CD8 versus CD4 co-receptors. The interaction of CD8 and CD4 with class I and class II molecules, respectively, is required for positive thymic selection, and also enhances the interaction of mature $CD4^+$ and $CD8^+$ T cells with antigen-presenting cells (APC).

Humans possess about 10^{11} mature T cells, representing approximately 10^8 clones with distinct TCRs (making an average clone size of 1000) (Arstila et al. 1999; Img et al. 2000). Each T cell expresses approximately 10^5 TCRs. T cells can be triggered by APCs expressing about 10–100 class I molecules containing an appropriate peptide. This is truly an amazing feat because, first, the T cell must sort through the roughly 10^5 class I molecules on the APC surface that contain inappropriate peptides, and, second, the affinity of the TCR for its cognate peptide–class I complex is such that contact is maintained only for the order of a few seconds to minutes.

It is important to distinguish two types of $CD8^+$ T-cell activation. 'Afferent' refers to the activation of resting naïve or memory $CD8^+$ T cells. 'Efferent' refers to the activation of $CD8^+$ T-cell effector function by target cells. In both cases activation requires ligation of the TCR by an appropriate MHC–peptide complex. Afferent activation requires additional 'co-stimulatory' signals that are transmitted by molecules normally expressed only by professional APCs (pAPC). The most important co-stimulatory interaction is that of CD28 on the $CD8^+$ T cells with CD80 or CD86 on the pAPC. The pAPCs are bone marrow-derived cells that normally activate $CD8^+$ T cells in lymphoid organs, typically a local draining node or the spleen. These include macrophages, B cells, and dendritic cells (DC). Unlike other cell types, pAPCs constitutively express MHC class II molecules, which enables them to present antigens to $CD4^+$ T cells, and to serve as a bridge between $CD4^+$ and $CD8^+$ T cells.

DCs are believed to play a particularly important role in generating $CD8^+$ T-cell responses. Large numbers are present in tissues, where they can form an interdigitating network. Such networks have been shown to exist in the skin (where the DCs are known as Langerhans' cells) and the respiratory tract. At the early stages of inflammation DCs 'mature', altering their phenotype and physiology as they migrate via lymphatics to local draining lymph nodes, where they activate T cells. Importantly, pAPCs are able to present both 'endogenous' viral antigens, i.e. peptides synthesized by the cell as a result of viral infection, as well as 'exogenous antigens', peptides, or polypeptides acquired from other virus-infected cells. This latter pathway is known as 'crosspriming', and it appears to be the principal pathway used to induce $CD8^+$ T cells when viruses are unable to initiate infection in pAPCs, or when viruses express gene products that interfere with antigen presentation by infected pAPCs.

A critical feature of $CD8^+$ T-cell responses to viruses (and probably other pathogens) is that only a tiny fraction (ranging from a few to perhaps 50 or so) of the thousands to hundreds of thousands of different peptides (depending on the complexity of the virus) generated by infected cells induce measurable $CD8^+$ T-cell responses. This phenomenon, known as immunodominance, is caused by a number of factors (Yewdell and Bennink 1999). The most important is that that only about 0.5 percent of peptides of the correct length bind to any given class I molecule allele with sufficient affinity ($K_D > 5 (10^{-7})$) to produce enough complexes to trigger $CD8^+$ T-cell activation. Second, the TCR repertoire can distinguish as foreign only about 50 percent of viral peptides that bind to class I molecules at or above this threshold affinity. Third, the antigen-processing machinery is limiting for production of 80 percent of the determinants that bind to class I molecules, mostly as a result of difficulties in proteolytic generation of determinants. Fourth, strong $CD8^+$ T-cell responses to a given determinant suppress responses to other determinants (this is known as immunodomination). Finally, to maximize replication, many viruses shut down the synthesis of host proteins, including class I molecules. If the supply of class I molecules is limiting, determinants from viral proteins expressed late in the infectious cycle will have no means of presentation to $CD8^+$ T cells (this applies only to cases in which $CD8^+$ T-cell activation requires presentation of endogenous antigens by pAPCs).

ANTIGEN PROCESSING: STEP BY STEP

The tripartite complex

CLASS I STRUCTURE

Class I molecules recognized by TCRs have three noncovalently bound chains. In order of size they consist of an oligopeptide of 8–12 residues, an invariant small soluble subunit (termed 'β_2-microglobulin'), and a membrane-bound integral membrane glycoprotein (termed 'α chain') encoded by highly variable genes. α chains consist of a short carboxy-terminal short domain, a typical transmembrane hydrophobic region, a relatively large extracellular domain, and an amino-terminal signal peptide that is cleaved upon import of class I molecules into the endoplasmic reticulum (ER). The three-dimensional structures of the extracellular domains of numerous class I allomorphs have been determined at high resolution by X-ray crystallography (the intracellular and transmembrane domains are excluded to enable crystal formation) (Madden 1995) (Figure 1). The stalk of the molecule is formed by the domain most proximal to the membrane, which is composed of residues encoded by the third of the seven exons that encode the α chain (and therefore termed the 'α3 domain'). The α3 domain makes important contacts with β_2-microglobulin and is the region that interacts with CD8. Residues from the first two exons (α1 and α2) combine to form the region most distal from the membrane, which is at its tip and contains the peptide-binding groove. The groove consists of two anti-parallel α helices which border a floor consisting of 7-β sheets. This region of the molecule contains most of the polymorphic residues, which are concentrated in areas of the groove that contact peptides.

α Chains are encoded by the MHC, termed human leukocyte antigen (HLA) in humans (Figure 2) and H-2 in mice, located, respectively on chromosomes 6 and 17. Three loci in the HLA encode class I genes, termed HLA-A, -B, and -C, whereas H-2 has two or three such loci (depending on the strain), termed H-2K, -D, or -L. At each α chain locus there are thousands of alleles present at appreciable frequencies in the entire

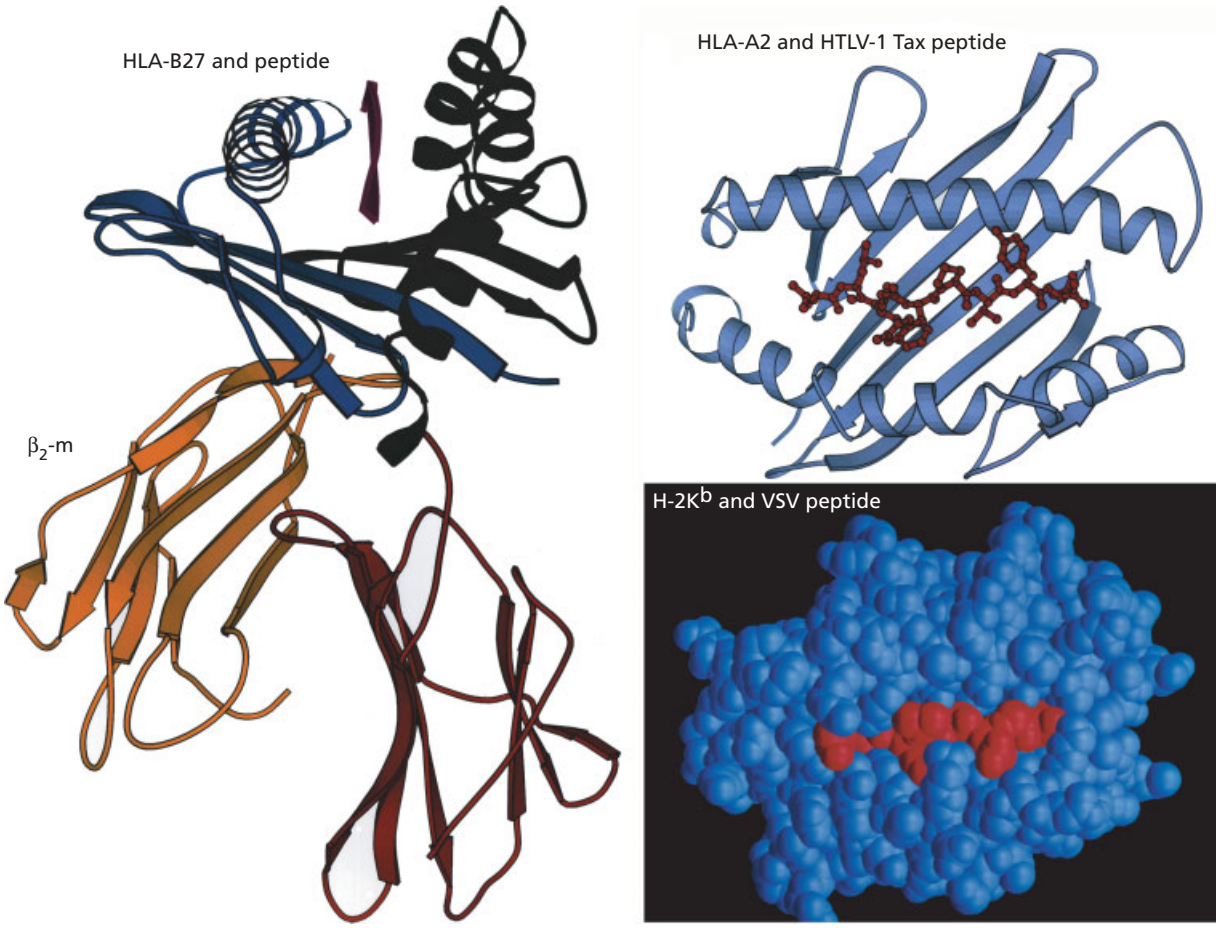

Figure 1 *Three-dimensional structure of MHC class I and class II molecules: structure of α-carbon backbone of HLA-B27 molecule (left) bearing an antigenic peptide (short red ribbon) in the groove, as determined by X-ray crystallography of water-soluble molecules released from the cell surface by protease digestion. Molecule is oriented with top toward the T-cell receptor (TCR). On the right are ribbon (top) and space-filling (bottom) models of peptides snug in the grooves of the class I molecules as they would be seen by the TCR.*

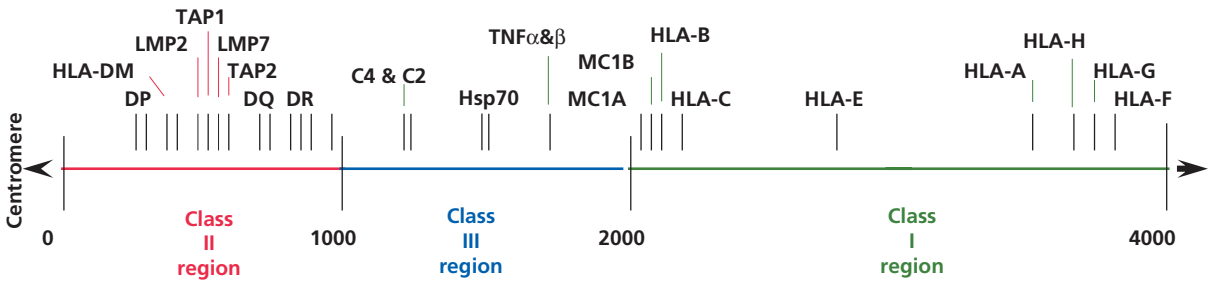

Figure 2 *Genetic map of HLA complex.*

human population. Individual ethnic groups often possess certain alleles that are present at higher frequencies than in the overall population. As the functions of HLA-A, -B, and -C molecules are similar, it is useful to lump together all the alleles produced by the three loci under the term 'allomorph'. HLA allomorphs are designated by a logical series of numbers (mercifully) that distinguish allelic alterations in nonsynonymous and synonymous alteration in coding regions and alterations in noncoding regions (see Table 1), whereas H-2 allomorphs are identified by a bewildering array of capital letters and superscripts, a nomenclature worthy of Torquemada.

The α chains under discussion are components of 'classical' class I molecules, also known as class Ia molecules (referred to throughout this chapter simply as class I molecules). In addition, there are a number of other homologous genes encoding α chains that generate 'nonclassic' or class Ib molecules. In general, class Ib genes are much less polymorphic than class Ia genes (although there are exceptions). The HLA encodes five such molecules: HLA-E, -F, and -G, which bind β_2-microglobulin, and MHC class I chain-related (MIC) gene products MICA and MICB, which do not (MIC is also of interest because its genes are highly polymorphic). All these genes have immunological functions that for are the most part independent of recognition by T cells with αβ TCRs. In addition, genes outside the MHC encode class Ib molecules: these include genes with immunological functions (such as *CD1*) and those apparently without direct immune function (such as *HFE*, which functions in iron metabolism). Mice have more than 40 genes encoding class Ib α chains; current understanding of the functions of these molecules ranges from fragmentary to nil.

CLASS I PEPTIDE LIGANDS

Binding rules

Peptides recovered from class I molecules are a highly heterogeneous mixture. Given a cell with 10^5 class I molecules of a given allomorph, there will be perhaps 10 000 distinct peptides presented. The dominant anchor residues of peptides bound by numerous HLA class I allomorphs have been determined by Edman sequencing of peptide pools recovered from purified molecules (Engelhard 1994; Rammensee et al. 1995) (the exact sequence of peptides of sufficient abundance can be determined directly by mass spectroscopy). In recent years, mass spectroscopy has been increasingly used to identify peptide ligands, as a result of the rapid technical advances in mass spectroscopy and greater access to advanced mass spectrometers. To date, however, only a few antigenic peptides from viruses have been identified in this manner.

The binding of peptides to class I molecules displays two important features. First, main chain atoms at the carboxyl and amino termini of the peptide make energetically important bonds with invariant residues at the ends of the groove (Bouvier and Wiley 1994). Peptides of fewer than eight residues cannot simultaneously contact both ends of the groove. Elongation of peptides also prevents these interactions because only a limited amount of kinking is allowed. Consequently, class I peptides exhibit little size heterogeneity, with about 90 percent of the peptides recovered from class I molecules falling within the range 8–11 residues in length, depending on the class I allomorph and the ability of peptides to bend in the groove. Second, the residues that demonstrate the most polymorphism among allomorphs form two to three deep pockets in the bottom of the groove which accommodate a highly restricted set of amino acids from bound peptides. As a result, each class I allomorph demonstrates a distinct preference for peptides that possess the complementary 'dominant anchor' residues, one of which is usually located at the carboxyl terminus (Table 1).

If antiviral $CD8^+$ T cells are known to be specific for a given viral protein presented by an allomorph with defined anchor residues, predictive algorithms (based largely on dominant anchor residues) can be used to identify a reasonably small number of candidate peptides from the protein (depending on the size of the viral protein, there are usually two to five such peptides) (Rammensee et al. 1997). These peptides can then be synthesized and used to determine the precise peptide recognized by virus-specific $CD8^+$ T cells. This method is used routinely, and is able to identify about 50 percent

Table 1 *Human MHC class I-binding peptide motifs*

	Position									
HLA molecule	**1**	**2**	**3**	**4**	**5**	**6**	**7**	**8**	**9**	**10**

HLA-Cw*0602									L	
HLA-Cw*0702									Y	

Human MHC molecules are termed 'human leukocyte antigens' (HLA). There are three loci encoding class I molecules, HLA-A, B, and C. Originally HLA molecules were typed serologically; such antigenically defined gene products are identified by one or two digits. More recently, HLA gene products are identified indirectly by genotyping. This provides much greater precision and revealed that previously identified alleles comprised a number of closely related genes. HLA genes (as opposed to gene products) are designated by an asterisk, and are numbered with up to seven digits. Closely related alleles share the first two digits and are discriminated by the last two digits (the remaining three digits are used to designate synonymous alterations in coding regions, or changes in noncoding regions), e.g. there are 30 known genes closely related to the canonical HLA-A2; these are numbered A0201 to A0230. HLA-C genes are given a gratuitous 'w' to avoid confusion with complement components. The anchor residues favor binding to various human class I allomorphs as determined by pooled sequencing of peptides eluted from purified class I molecules. The presence of anchor residues at consecutive positions at residues at consecutive positions at the carboxyl terminus reflects heterogeneity in peptide length, and not consecutive anchor positions.

of the determinants recognized by antiviral $CD8^+$ T cells. If this method fails, overlapping peptides covering the entire protein can be screened for activity. Empirically it has been found that peptides of 13 residues overlapping by 9–10 residues work well.

Exogenous peptide presentation: practical issues

All cells expressing class I molecules possess cell-surface class I molecules capable of binding peptides present in the extracellular fluids. Free peptides are probably rarely present in sufficient concentrations in vivo during a virus infection to sensitize bystander cells. Although the physiological significance of such peptide-receptive (PR) cell surface class I molecules is uncertain, PR class I molecules enable the use of synthetic peptides to sensitize cells to activate $CD8^+$ T cells for in vitro assays (lysis, intracellular cytokine staining, ELISPOT), and to stimulate secondary in vitro responses (an oft-used method to generate $CD8^+$ T cells specific for a known peptide, and an alternate method for determining which peptides are recognized by $CD8^+$ T cells). The expression of cell surface PR molecules can be enhanced by culturing cells at 25–28°C in media supplemented with 2–5 μg/ml human β_2-microglobulin.

Immunogenic peptides typically bind to class I molecules with a K_D of $<10^{-7}$ mol/l. Using optimized systems, most antiviral effector $CD8^+$ T cells require only 10–1000 peptide–class I complexes for activation. Translated into practical terms, incubating cells with sub-nanomolar (often picomolar) concentrations of peptide is sufficient for activation of effector $CD8^+$ T cells. This enables screening of peptides with 13 residues, based on the generation of fragments by serum proteases in culture media (Kozlowski et al. 1992), or low-affinity binding of extended suboptimal peptides. It also means that for screening purposes highly purified peptides need not be used (though, if impure peptides are used to generate $CD8^+$ T cells, they may induce $CD8^+$ T cells that are specific for contaminants (Chen et al. 1996)). Note that great care has to be taken when working with synthetic peptides corresponding to naturally processed peptides, which when present in a 1 mmol/l stock solution often represent a billionfold excess. Care must also be taken when weighing out the peptides, which are notoriously susceptible to floating away on errant air currents, where the tiniest speck can contaminate fluids. If possible, the balance should not be located in rooms used to perform assays or culture target cells. Incubation of cells with a vast excess of peptide can lead to spurious recognition by $CD8^+$ T cells specific for other determinants. Consequently, it is important to establish that $CD8^+$ T cells recognize cells sensitized with a concentration of peptide that results in the generation of a physiological number of peptide–class I complexes; usually this means incubating cells with sub-nanomolar peptide concentrations. Ultimately, definitive evidence that $CD8^+$ T cells recognize a given determinant in a protein requires the demonstration that mutating the corresponding residues in a protein modifies antigenicity. Lamentably, this rigorous approach is rarely applied.

Determinants that fail to be identified using synthetic peptides may possess post-translational modifications required for binding to class I molecules and/or recognition by the cognate TCR. These include phosphorylation, glycosylation, or deglycosylation of N-linked oligosaccharides, which converts asparagine residues that serve as the branch point for N-linked oligosaccharides into aspartic acid (Skipper et al. 1996; Andersen et al. 1999; Zarling et al. 2000). Cysteine-containing peptides (about 15 percent of all antigenic peptides) present special challenges as a result of the highly reactive nature of the free sulfhydryl group. $CD8^+$ T cells may recognize cysteine-crosslinked peptide dimers, cysteinylated peptides, or other undefined post-translational modifications (Meadows et al. 1997; Chen et al. 1999). Another potential reason for failing to locate a determinant in a protein is that the peptide is encoded by an alternate reading frame (Mayrand and Green 1998).

Although the basis for the antigenicity of synthetic peptides is nearly always their binding to cell-surface PR molecules, unless the cells are incubated with peptides at low temperature, peptides will traffic to endosomal compartments as a result of constitutive endocytosis and also to the ER (Day et al. 1997), where they can associate with resident PR molecules.

CLASS I ASSEMBLY AND SURFACE EXPRESSION

As with most integral membrane proteins, α chains are co-translationally inserted into the ER via the translocon. HLA α chains acquire a single N-linked oligosaccharide during translocation, whereas H-2 α chains are either di- or triglycyosylated. Newly synthesized α chains initially bind to calnexin, an abundant general purpose ER molecular chaperone which, like other chaperones, is thought to facilitate proper folding by preventing inappropriate interactions between hydrophobic domains (Williams and Watts 1995) (Figure 3). Within 5–10 min, α chains associate with β_2-microglobulin, and are transferred from calnexin to a complex of calreticulin, ERp56 (two more general purpose chaperones), and tapasin, a chaperone dedicated to class I molecules (Pamer and Cresswell 1998). ERp56 catalyzes the proper disulfide bond formation in α chains (Hughes and Cresswell 1998), whereas tapasin mediates the binding of the assembly complex to transporter associated with antigen processing (TAP). $\alpha\beta_2$-microglobulin heterodimers remain in the ER tethered to TAP until their release is triggered by peptide binding (Ortmann et al. 1994; Suh et al. 1994). Class I departure from the ER appears to be subject to further quality control inspection at ER exit sites (Spiliotis et al. 2001). Depending on the class I allomorph and the supply of peptides (and probably other undefined factors), class I export from the ER can take between 10 min and several hours. Transport to the cell surface via the Golgi complex occurs over a period of 10–20 min. The degree of association of class I molecules with tapasin (and therefore TAP) varies considerably among allomorphs (Peh et al. 1998). Why this should be remains an interesting mystery. Although tapasin is not absolutely required for peptide binding, it facilitates the loading of high-affinity peptides through an undefined mechanism (Garbi et al. 2000; Grandea et al. 2000).

'High-affinity' peptide binding refers to a K_D of $<10^{-7}$ mol/l. Peptide ligands that bind with this affinity will not dissociate from class I heterodimers for hours, and those with higher affinities will on average probably remain bound to class I until the molecule is shed from the cell surface or destroyed after internalization into lysosomes, which occurs with a half-time of the order of tens of hours. It is likely, however, that a substantial portion of peptides binds class I molecules less stably. Once peptides dissociate from cell surface class I molecules, class I molecules are unstable and unfold with a time of about 10 min. Just before unfolding β_2-microglobulin dissociates from heavy chains, which denature rapidly in its absence. This process is reversible, which is

why β_2-microglobulin promotes the formation of PR molecules. β_2-Microglobulin is naturally present in human and mouse serum and plasma (and fetal bovine serum) at concentrations that create such PR class I molecules. Increasing the β_2-microglobulin concentration enhances the formation of PR molecules, as discussed above. Human β_2-microglobulin is preferred for this purpose because of its commercial availability and because it binds more tightly to both human and mouse α chains than mouse β_2-microglobulin, and it is thus more efficient at creating PR class I molecules.

Generating peptide ligands from biosynthesized proteins

SOURCE OF ANTIGENIC PEPTIDES

The process by which peptides are derived from proteins and delivered to class I molecules (or, for that matter, MHC class II molecules) is termed 'antigen processing' (Yewdell and Bennink 1992; Germain and Margulies 1993; Heemels and Ploegh 1995; Pamer and Cresswell 1998; Yewdell et al. 1999a). The classic class I antigen-processing pathway begins in the cytosol (see Figure 3). Proteins can reach the cytosol by virtue of being either synthesized by ribosomes (endogenous antigens) or physically introduced into the cytosol from extracellular fluids (exogenous antigens).

Antigenic peptides can be derived from any type of viral or cellular protein, including those located in the cytosol, nucleus, mitochondria, and various membranes. Even secreted proteins can be highly antigenic. How are peptides generated from these disparate protein sources? A possible clue comes from the kinetics of presentation of newly synthesized viral proteins to $CD8^+$ T cells, which can occur within an hour of adding a virus to cells. Given the time needed for viral penetration and transcription (using DNA or negative strand RNA viruses) and transport of class I–peptide complexes from the ER to the cell surface, this leaves only about 30 min for the virus to begin to synthesize its proteins. If viral proteins were simply entering the steady-state pool of proteins present in a cell, and had to compete with cellular proteins for access to class I molecules, it is difficult to understand how presentation could occur so rapidly.

One potential solution would be that peptides are derived from viral proteins that are much less stable than the cellular proteins with which they compete for access to MHC class I molecules. But, in fact, antigenic peptides are usually derived from viral proteins that are extremely stable when measured by standard means. Another solution, originally proposed by Van Pel and Boon (1989), is that antigenic peptides are derived from short-lived, misbegotten out-of-frame polypeptides that result from errors in transcription or translation. This probably occurs (Mayrand and Green 1998), but it does not account for the vast majority of peptide ligands that are translated in the correct reading frame (Rammensee et al. 1997).

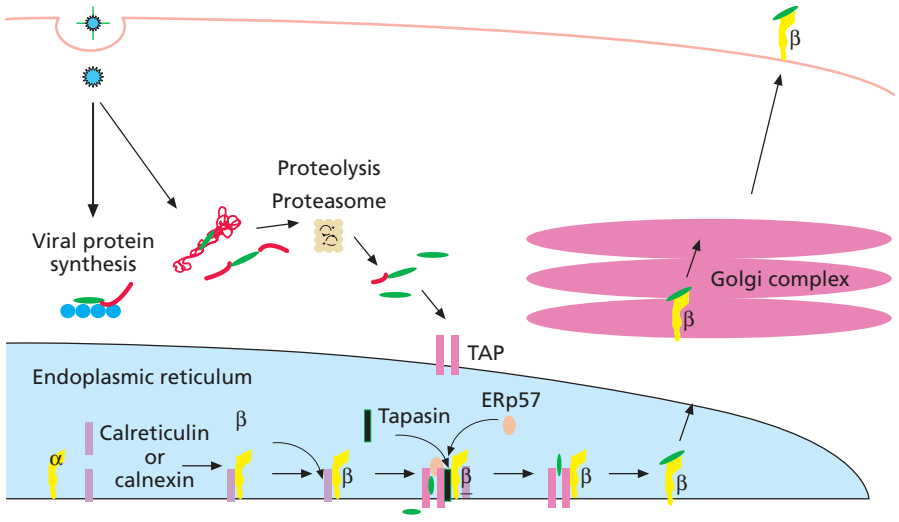

Figure 3 *Class I antigen-processing pathway: at the top left of the figure, a virion is shown entering the cell via endocytosis, and beneath it a viral capsid (blue burr with white border) is shown entering the cytosol (with enveloped viruses this is a consequence of fusion of viral and endosomal membranes; with nonenveloped viruses, the virus directly breaches the cellular membrane). In most situations, the major source of antigenic peptides (green oval) is protein synthesis (major arrow emanating from capsid), but peptides can be derived from capsid proteins if sufficient quantities are delivered to the cytosol. Many, and perhaps most, peptides are probably derived from defective forms of newly synthesized proteins (Schubert et al. 2000). Proteasomes are the major producer of peptide in the cytosol, but other proteases may also contribute. In particular, aminopeptidases can trim proteasome products. Cytosolic peptides of 8–17 amino acids are transported into the endoplasmic reticulum (ER) by TAP (transporter associated with antigen processing), where trimming by aminopeptidases can also occur. Peptides bind to newly synthesized class I $\alpha\beta_2$-microglobulin heterodimers, which are released from TAP and transported via the Golgi complex to the cell surface for immune perusal.*

An alternate solution is that protein biosynthesis, like all biological processes, is imperfect. A certain percentage of ribosomal products must be defective in some way and not reach their stable conformation. It has been known for years that introducing alterations in proteins, which increases their degradation in cells, increases their presentation to $CD8^+$ T cells (Tevethia et al. 1983; Townsend et al. 1986, 1988), with the implication that imperfect forms of proteins generated from wild-type genes would be a preferred source of antigenic peptides. Many different types of errors can be envisaged in mRNA generation (misincorporation of nucleotides, missplicing), or in the process of protein synthesis itself that results in the misincorporation of amino acids, premature termination, or deletion of residues. In addition, many proteins are members of multi-subunit complexes, and there must be imbalances in synthesis that result in an excess of certain subunits which are unstable in the absence of their normal partners. Additional mistakes must be made in protein targeting, such that proteins are delivered to the wrong organelle, where they misfold and are targeted for destruction. The folding of nascent proteins in the crowded environment of the cytosol is more difficult than folding in a homogeneous solution in vitro, and there are ample opportunities for the process to go awry, particularly for large multi-domain proteins.

The products of these errors can be grouped together as a source of antigenic peptides, because they will all presumably be degraded by proteasomes and other cellular proteases contributing to quality control. Such substrates have been termed defective ribosomal products (DRiP) (Yewdell et al. 1996). The beauty of DRiPs for the immune system is that they enable MHC class I molecules to monitor protein synthesis rates in cells and not protein concentrations. In this way, viral infections could be detected as soon as possible, particularly as many viruses rapidly monopolize the protein synthesis machinery to produce their own gene products. This would explain the rapid detection of virus-infected cells by $CD8^+$ T cells and also the generation of antigenic peptides from a huge variety of viral proteins, regardless of their apparent metabolic stability or intracellular targeting.

Note that DRiPs are not exclusively limited to viral proteins, but rather they are an inevitable consequence of synthesizing *any* protein. Indeed, the average viral protein may be less prone to DRiP formation than the average cellular protein. An additional strength of the DRiP hypothesis is that it provides an explanation for why class I peptide ligands are not biased toward originating from metabolically unstable proteins. There is experimental evidence to support the idea that DRiPs provide a significant source of peptide ligands to MHC class I molecules. First, 30 percent or more of the total pool of newly synthesized cellular proteins appear to be degraded within a few minutes of their synthesis, as inferred by the increased recovery of radiolabeled proteins from cells treated with proteasome inhibitors. An increased fraction of newly synthesized proteins recovered from proteasome inhibitor-treated cells were polyubiquitylated, as predicted (the ubiquitin–proteasome system is discussed below) (Schubert et al. 2000). Second, blocking protein synthesis reduces the supply of peptide ligands for TAP or class I molecules (Reits et al. 2000; Schubert et al. 2000). Third, using cells expressing a gene under the control of a repressible promoter, the rate of peptide generation from the gene is proportional to the amount of mRNA, not the level of the source protein (Khan et al. 2001). Fourth, presentation of viral peptides is tightly linked to the rate of translation of the source gene product and not the steady state level of stable protein (Princiotta et al. 2003).

This is not to say that DRiPs are the only source of antigenic peptides; clearly they are not. For all we know, on average, peptides might be more efficiently produced from long-lived proteins. Indeed, it is to be expected that the DRiP rate will vary tremendously between different proteins. For proteins with low DRiP rates, the bulk of peptides will probably be derived from the classic turnover of proteins, and vice versa for proteins with high DRiP rates.

What about secreted proteins?

Many viral proteins are targeted to the ER for secretion or insertion into membranes used for viral maturation. Depending on the cell type, a high percentage of cellular proteins can be similarly targeted. Despite their targeting, antigenic peptides can be derived from these proteins with similar efficiency as nuclear or cytosolic proteins. How are such proteins processed?

As discussed below, the secretory pathway has a limited capacity for generating peptides from full-length proteins. Consequently, in a high percentage of cases, processing of ER-targeted proteins occurs in the cytosol (this represents a subset of DRiPs). There are two general mechanisms for delivering such proteins to the cytosol: either they are diverted to the cytosol on their way to the ER or they are returned to the cytosol after visiting the ER. Although only a few studies have examined this question, it appears that the latter route is the more traveled (Bacik et al. 1997; Mosse et al. 1998).

This is consistent with the recent appreciation that degradation of ER proteins occurs in the cytosol after the re-export of the protein through the translocon (Brodsky and McCracken 1999). Ironically, even class I molecules are degraded through this mechanism (Hughes et al. 1997), a process greatly accelerated by the action of some viral proteins (Wiertz et al. 1996).

THE UBIQUITIN–PROTEASOME PATHWAY

The axe

Proteasomes are the principal mechanism used by eukaryotic cells to degrade proteins. In so doing, they

provide a major source of class I peptide ligands or their precursors (Rock and Goldberg 1999). Proteasomes are ancient structures, present in all eukaryotes and in many prokaryotic species as well (Voges et al. 1999). They are abundant in eukaryotic cells, e.g. HeLa cells contain approximately 500 000. They are present in both the nucleus and the cytosol, where many bind to the ER: where they may be involved in process of retro-translocation of misfolded ER proteins to the cytosol.

Proteasomes are remarkable machines, capable of degrading a wide variety of protein substrates; indeed, few proteins (if any) are known to be resistant to the action of proteasomes. The cleavage reactions occur in a barrel-like structure known as the 20-S proteasome, and regulatory subunits that attach to each end of the 20-S proteasome. The 20-S proteasomes contain 14 distinct subunits arrayed in a four-ring structure of the type, $\alpha_7\beta_7\beta_7\alpha_7$. Three of the β subunits in each inner ring are known to be catalytically active, with their active sites facing a central chamber in which proteins are degraded.

Given their ability to degrade virtually anything, 20-S proteasomes are potentially extremely dangerous to cells, and safeguards prevent such proteolytic rampages. The catalytic subunits are synthesized with pre-sequences that must be cleaved during the assembly process to activate proteolytic activity. The barrels are closed at both ends, and they must bind to a 19-S regulatory particle for protein substrates to gain access to the central chamber. The 20-S subunits bind to one 19-S subunit on each end to form the 26-S proteasome – the active form of proteasomes in cells. Why proteasomes exhibit dyad symmetry is unclear. The generation of a proteolytic chamber from symmetrical components is a parsimonious solution which is used by organisms to generate other barrel-like assemblies used for protein degradation or folding. The binding of two 19-S subunits may simply follow from the symmetry of 20-S proteasomes and not add much to proteasome function. Alternately, if the 19-S subunit processing of the protein is the rate-limiting step in protein degradation, having two 19-S submits may optimize the use of the 20-S subunit.

Unlike most proteases, the 26-S proteasome degrades substrates in an energy-dependent manner that utilizes adenosine triphosphate (ATP). ATP is exclusively consumed by the 19-S subunit, which recognizes potential substrates bearing polyubiquitin chains, unfolds the substrates, and feeds them, spaghetti like, into the barrel of the 20-S proteasome via the narrow portal that is opened as part of the process (Glickman et al. 1999). At some point before this event, the polyubiquitin chains are removed from the substrate and the ubiquitin is returned to the pool of ubiquitin monomers for reuse.

Proteasomes come in multiple forms. Indeed, the initial evidence implicating proteasomes in antigen processing was the discovery of the MHC-encoded proteasome subunits and that their expression (and that of a third subunit) is enhanced by exposure of cells to interferon γ (IFN)-γ or tumor necrosis factor (TNF)-α, the predominant cytokines released by activated $CD8^+$ T cells (Monaco and Nandi 1995) (these cytokines upregulate transcription of genes encoding each of the components of the class I processing pathway, which share common promoter elements). When induced, these subunits replace constitutively expressed subunits to create 20-S 'immunoproteasomes', which appear to be better at producing peptides favored by MHC class I molecules (Tanaka and Kasahara 1998). Such immunoproteasomes can be created only from scratch, because subunit exchange in mature proteasomes is not known to occur. As proteasomes are extremely long lived (half-life of about 10 days), cells exposed to cytokines will possess a mixture of standard proteasomes and immunoproteasomes for a very long time. Although some defined determinants are produced more efficiently by immunoproteasomes, other determinants are produced less efficiently.

Cytokine-exposed cells also produce 11-S regulators, which can take the place of 19-S regulators on 20-S proteasomes. Expression of 11-S regulators has been shown to favor antigen presentation through undefined mechanisms (Rechsteiner et al. 2000). It has been proposed that 11-S and 19-S regulators bind to a single 20-S subunit to form hybrid proteasomes, with the 11-S regulator serving to attach proteasomes to TAP and thereby increase the efficiency of peptide delivery.

The handle

Ubiquitin is a 76-residue protein that is remarkably well conserved among eukaryotes – yeast ubiquitin differs from human ubiquitin by only three conservative substitutions. It is extremely abundant in cells (about 10^8 copies per HeLa cell (Haas and Bright 1985)), and its many known cellular functions that revolve around covalent conjugation to the ϵ-NH_2 groups of lysine residues (or the amino terminus of proteins) via its carboxyl terminus (Hershko and Ciechanover 1998). Ubiquitin itself is ubiquitylated and, when polyubiquitin 'trees' containing four or more ubiquitins are present on proteins, they bind to 19-S regulators that deliver the protein to proteasomes for destruction, whereas the ubiquitin is recycled (Thrower et al. 2000). Given its dire consequences, polyubiquitylation of proteins would be expected to be a highly regulated and complicated affair and, indeed, numerous gene products are devoted to ubiquitin conjugation. For obscure reasons, cells are not content to add a single ubiquitin tree to proteins destined for destruction. Rather, polyubiquitylation is highly heterogeneous, and trees of different sizes are added to multiple substrate sites in what appears to be an irregular manner, such that polyubiquitylated proteins usually migrate as a ladder (or smear) in sodium dodecylsulfate–polyacrylamide gel electrophoresis (SDS-PAGE). Moreover, the process is not

irreversible, and enzymes capable of removing ubiquitin from proteins (ubiquitin hydrolases) are highly active in cells (Wilkinson 2000). Polyubiquitylation is not an absolute prerequisite for protein degradation by proteasomes. There are only a few specific examples of such ubiquitin-independent targeting at present, but this could well prove to be a major source of proteasome substrates (Verma and Deshaies 2000; Benaroudj et al. 2001).

Role of proteasomes in generating antigenic peptides

The contributions of proteasomes to antigen processing, and indeed mammalian cell physiology, have been defined largely through the use of membrane-permeant, low-molecular-weight inhibitors of the proteolytic activities of 26-S proteasomes (Bogyo et al. 1997; Goldberg and Rock 2002). These include natural products of microorganisms and synthetic oligopeptide-based compounds. The former usually exhibit far more specificity for the proteasome than the latter. There are two major problems in using proteasome inhibitors to study cellular processes. First, proteasome inhibitors, like other inhibitors, cannot be absolutely specific for a single target, and they must interact with other cellular targets. It is possible to control for nonproteasome-related effects in that proteasome inhibitors with distinct chemical structures give similar results. Second, proteasomes play a key role in many cellular processes, and blocking them rapidly induces a number of serious secondary effects. These effects include depletion of the pool of free ubiquitin available for protein conjugation, induction of molecular chaperones, inhibition of protein synthesis, and interference with the cell cycle and signaling. That some of these effects are likely to be caused by an accumulation of ubiquitylated substrates awaiting destruction does not simplify matters. These effects can be minimized (although not necessarily made insignificant) by minimizing the time for which cells are exposed to proteasome inhibitors.

Proteasome inhibitors have been used to demonstrate that proteasomes are the principal cytosolic protease used by cells for generating MHC class I peptide ligands (Rock et al. 1994; Rock and Goldberg 1999). Peptide generation is maintained, however, in the presence of proteasome inhibitors, but at a lower rate. This varies in a class I allomorph-specific manner. There are many examples of antigenic peptides whose generation is unimpeded or even enhanced by proteasome inhibitors. In the latter case it has been documented for several examples that proteasomes can function to destroy determinants. These findings have two interpretations that are not mutually exclusive. First, alternate cellular endoproteases may participate in antigen processing. Second, it may not be possible completely to block proteasome function with the inhibitors currently in use. This may be the result of either resistant activities in individual proteasomes or the existence of a subset of proteasomes immune to the effects of the inhibitors, resulting perhaps from inaccessibility.

In vitro studies with isolated 20-S proteasomes have shown that proteasomes can generate the precise peptides presented by MHC class I molecules. This process is not very efficient, however, and extended versions, particularly peptides with amino-terminal extensions, are more likely to be produced. The 20-S proteasomes from yeast generate a similar set of peptides to mammalian proteasomes, deflating the hopes of immunologists that proteasomes (at least standard proteasomes) evolved for the purpose of generating antigenic peptides. Given its numerous subunits, it might be expected that proteasomal cleavage be governed by complex rules. Proteasomes do not disappoint in this regard. Proteasome activity for individual peptide bonds is influenced by amino acids on both sides of the cleavage site, as wells as flanking residues, with the greatest influence mediated by those within five residues of the cleavage sites. Work is progressing on developing predictive algorithms for the peptides that are liberated by proteasomes (Altuvia and Margalit 2000; Kuttler et al. 2000).

ROLE OF NONPROTEASOMAL CYTOSOLIC PROTEASES IN ANTIGEN PROCESSING

Trimming enzymes

Proteasomes need not generate the precise peptides presented by class I molecules. A considerable body of evidence indicates that peptides can be trimmed by aminopeptidases in the cytosol (York et al. 1999) and ER (Yewdell et al. 1999a), whereas carboxypeptidase trimming seems to be highly unusual. A candidate cytosolic aminopeptidase is leucyl aminopeptidase, because its expression is enhanced by IFN-γ and TNF (Beninga et al. 1998). Other aminopeptidases (bleomycin hydrolase and puromycin-sensitive aminopeptidases) are known to be capable of trimming amino-terminal extensions from defined antigenic peptides (Stoltze et al. 2000). The ER contains two aminopeptidases (ERAP1 and ERAP2) that are largely, if not exclusively, dedicated to trimming antigenic peptides (Serwold et al. 2002; York et al. 2002).

One of the most striking features of antigen processing is that the recovery of antigenic peptides from cells is dependent on expression of a class I molecule that binds the peptide with more than the threshold affinity. Two mechanisms potentially contribute to this phenomenon (Falk et al. 1990):

1. class I molecules are required for the generation of antigenic peptides by serving as a template for the action of trimming exopeptidases
2. peptides are rapidly destroyed unless they are protected by class I molecules.

It appears that the second possibility plays a major role in the phenomenon. Class I molecules are still required for the recovery of antigenic peptides when the antigenic peptides are synthesized as cytosolic minigene products corresponding to the exact peptide. Moreover, peptides are rapidly degraded by cytosolic extracts and rapidly exported from the ER unless they bind to class I molecules. Peptides can be destroyed by the very aminopeptidases involved in trimming, and also by endopeptidases active on oligopeptides. One such endopeptidase known to be capable of degrading antigenic peptides and their precursors is thimet oligopeptidase (Silva et al. 1999). Peptide destruction is probably a major contributor to the low efficiency of antigen processing discussed above.

Proteasome understudy?

As mentioned above, the generation of many class I peptide ligands is insensitive to proteasome inhibitors. Two groups reported that it is even possible to adapt cells to resist the cytotoxic effects of proteasome inhibitors (Glas et al. 1998; Geier et al. 1999). In both studies the adapted cells demonstrated enhanced expression of tripeptidyl peptidase (TPPII), which was proposed as a substitute for the functions of the proteasome. This was unexpected because proteasomes are essential for the viability of yeast. Subsequently it was shown that cells adapted to proteasome inhibitors retain proteasome activity and that such activity contributes to antigen processing and protein degradation and is required for viability (Princiotta et al. 2001). School is still out on the possible contributions of TPPII to antigen processing and overall protein degradation, though a recent report suggests that a majority of proteasome products must be further degraded by TPPII to be eligible for binding to class I molecules (Reits et al. 2004).

SHEPHERDING PEPTIDES TO THE PROMISED LAND: TAP

Endoplasmic reticulum trimming by aminopeptidases is possible because extended peptides have access to the ER. Peptides are transported from the cytosol to the ER by TAP, which is a member of a large family of prokaryotic and eukaryotic proteins (the ABC, or ATP-binding cassette, family) that function in the transmembrane transport of a wide variety of substrates (Elliott 1997). TAP is formed by the association of two homologous subunits termed TAP1 and TAP2 which rapidly assemble in the ER. Each subunit possesses multiple (9–10), short, membrane-spanning domains attached to a globular carboxy-terminal, cytosolic, nucleotide-binding domain.

As with other family members, TAP-mediated peptide transport is driven by hydrolysis of ATP or other trinucleotides. TAP preferentially transports the types of peptides favored by class I molecules, particularly in its requirements that peptides be at least eight residues in length. The upper limit of peptide length is messier, but the efficiency drops off considerably when peptides are longer than 16 residues or so, although even those with 40 residues may be transported at low efficiency (Koopmann et al. 1996).

TAP does not transport all peptides with equal efficiencies. Alterations at all positions can influence TAP-mediated transport. The greatest preferences are demonstrated for carboxy-terminal residues; indeed TAP from different species demonstrates a marked preference for the types of carboxyl termini preferred by their respective class I molecules (in humans, hydrophobic or positively charged residues) (Momburg et al. 1994; Schumacher et al. 1994). Thus, longer peptides transported into the ER by TAP are more likely to possess amino-terminal extensions than carboxy-terminal ones. Next in importance are the first three residues from the amino terminus. Similar preferences exist for peptides of different lengths. This suggests a model in which efficient TAP recognition of peptides entails interaction with the peptide's three amino-terminal residues and carboxy-terminal residue, and the presence of no less than 4, and no more than 12, internal spacer residues. Interestingly, despite the fact that proline at position 2 is a dominant anchor residue for numerous human class I allomorphs, this greatly disfavors TAP-mediated transport of many peptides. This suggests that, for these peptides, trimming of amino-terminal extensions in the ER is particularly important.

TAP polymorphism in rats greatly influences the peptides delivered to class I molecules (Howard 1995). Although human TAP genes display limited polymorphism, the known alleles do not appear to differ greatly in their specificities (Obst et al. 1995). Thus, it does not appear that TAP polymorphism plays a major role in influencing the response of individuals to viral proteins. A splice variant of human TAP2 has been described that possesses an altered carboxyl terminus (Yan et al. 1999). This looks to modify the specificity of TAP, but its effects in vivo await further characterization.

TAP-INDEPENDENT PROCESSING OF ENDOGENOUS ANTIGENS

As mentioned above, class I molecules are bound to TAP (via tapasin) until released by peptide binding. It is thought that this facilitates their association with peptides transported by the same complex, thereby greatly increasing the effective peptide concentration. TAP is not, however, essential for peptide loading on to class I molecules. Peptides targeted to the ER are able to associate efficiently with class I molecules in cells lacking TAP (Anderson et al. 1991). Indeed, in studies using recombinant vaccinia virus expressing various forms of a peptide antigen, peptides targeted to the ER have been found to be more immunogenic in mice than

cytosolic peptides biosynthesized in similar amounts, or the full-length gene viral proteins products that are the natural source of the peptides (Restifo et al. 1995). It has also been found that cytosolic antigens can be presented to a limited extent in a TAP-independent manner by an unknown mechanism. Although these exceptions are interesting and possibly of practical importance (using ER-targeted peptides for immunization), it should be emphasized that TAP plays a critical role in the presentation of most viral determinants. TAP is also crucial for T-cell development, because TAP-deficient individuals demonstrate greatly decreased levels of T cells (de la Salle et al. 1994; Gadola et al. 2000). Curiously, such individuals are relatively healthy, having mainly recurrent localized bacterial infections.

CONTRIBUTION OF SECRETORY PROTEASES TO ANTIGEN PROCESSING

Many proteins targeted to the ER immediately lose their amino-terminal signal sequences, presumably as a result of the action of signal peptidase. Further proteolysis of these peptides enables their binding to class I molecules, particularly if class I allomorphs favor binding of hydrophobic peptides. HLA-A2 is the prototype for these allomorphs, and many of the peptides that it presents are derived from signal sequences. Signal sequence presentation is central to the function of some class Ib molecules, which present leader peptides from class I molecules to natural killer (NK) cells.

The presentation of such leader peptides can be either TAP independent or TAP dependent. In the latter case, presentation can be either proteasome dependent or independent. Thus, signal peptides can be produced strictly by secretory proteases or a combination of secretory and cytosolic proteases.

From a functional standpoint, using ERAP the ER is able to trim amino-terminal extensions of TAP-transported peptides efficiently, while still having a very limited capacity for removing carboxy-terminal residues. Peptides transported into the ER independently of TAP appear to be handled in a similar manner.

The secretory pathway displays a limited capacity for generating determinants from very large substrates, presumably as a result of endopeptidases acting in concert with aminopeptidases. Such endopeptidases are not necessarily limited to the ER: furin, an endopeptidase activated only in the trans-Golgi complex, is involved in the generation of several defined peptides, which are presumably generated and loaded in the trans-Golgi complex (Gil-Torregrosa et al. 2000).

Generating peptide ligands from exogenous proteins

As mentioned at the start, the activation of naïve $CD8^+$ T cells requires pAPCs that express the proper co-stimulatory molecules (at least according to dogma). Obviously, such cells will present peptides from endogenous antigens synthesized during a viral infection. But, what if the virus cannot (or will not) infect the appropriate APC? And what about nonviral pathogens that do not hijack host ribosomes for their own nefarious ends? Can naïve $CD8^+$ T cells respond under these conditions?

The answer to this question is yes. This pathway was initially discovered by Bevan, who reported that $CD8^+$ T cells can be induced against antigens introduced into mice by adoptive transfer of MHC-mismatched cells, terming the phenomenon 'crosspriming' (Bevan 1976). Underlying this are a number of potential mechanisms that also serve as the basis for the immunogenicity of protein-based vaccines that elicit $CD8^+$ T-cell responses. The true nature of the crosspriming pathway in vivo remains to be determined, although it is likely that it reflects the operation of many (or all) of the mechanisms defined below.

TWO PATHS TO RIGHTEOUSNESS

The processing of exogenous antigens can be divided into two distinct pathways. First, antigens can access the cytosol where they are treated in a manner similar to endogenous antigens. Three basic routes into the cytosol are possible.

The first is traversing cell membranes as a result of properties associated with the substance, e.g. viruses or liposomes can fuse with cell membranes, delivering their contents to the cytosol. Other viruses directly penetrate cellular membranes. In the case of abundant viral core proteins, a sufficient quantity may enter the cytosol to produce enough MHC–class I complexes to trigger $CD8^+$ T cells (Yewdell et al. 1988; Riddell et al. 1991). Bacteria that reside in endosomal compartments secrete proteins that translocate endosomal members to gain access to the cytosol where they can alter cellular function (Pamer et al. 1991). Some proteins have sequences that enable them to cross the plasma membrane (Chikh et al. 2001). These sequences can enable even large proteins to cross membranes.

The second route entails entry from endosomes that leak by accident or by design. Highly active phagocytic cells create macropinosomes which enable substrate access to the cytosol (Norbury et al. 1995). DCs possess an apparently unique endocytic compartment that delivers substances of about 40 kDa to the cytosol (Rodriguez et al. 1999).

The third route is retrograde transport from endosomes to the Golgi complex and then to the ER, where they follow the route traversed by endoplasmic reticulum-associated degradation (ERAD) substrates back to the cytosol. Many toxins are thought to enter cells via this route (Lord and Roberts 1998).

Peptides can also be generated from exogenous antigens outside the APC or in endosomal compartments of

APCs and loaded on to cell surface or endosomal PR class I molecules. This pathway resembles the classic class II antigen-processing pathway. The pAPCs are particularly adept at such nonclassic class I antigen processing.

GENERATION AND TRAFFICKING OF PR CLASS I MOLECULES

Within 60 min of their departure from the ER, a substantial fraction of class I molecules lacks peptide ligands. These molecules may never have been loaded, may have been loaded with a lower affinity ligand, or may have suboptimally bound a peptide that normally binds with higher affinity. This is the source of PR class I molecules, the properties of which are described above. Interference with peptide supply by blocking proteasomes or inactivating TAP actually *decreases* the number of PR class I molecules (Day et al. 1995), presumably because less poorly loaded class I molecules leave the ER. The percentage of such poorly loaded molecules can be very high, representing even 95 percent of class I molecules exported from the ER (Su and Miller 2001).

Such PR molecules are present throughout the secretory pathway. As discussed above, exogenous β_2-microglobulin and/or low temperatures stabilize PR molecules. PR molecules stabilized in this manner also participate in the presentation of exogenous antigens processed in endosomal compartments (Song and Harding 1996; Schirmbeck et al. 1997). This latter statement alludes to the trafficking of class I molecules to endosomes. Class I molecules derived from the cell surface have been found in endosomal compartments that contain class II molecules in a number of cell types, including DCs (Geuze et al. 1985; Chiu et al. 1999; Gromme et al. 1999; Castellino et al. 2000; Kleijmeer et al. 2001; MacAry et al. 2001). A number of class I allomorphs have been reported to bind peptides at the acidic pH characteristic of endosomes (Stryhn et al. 1996), and the generation of peptide class I complexes in endosomes has been visualized (Castellino et al. 2000).

It is uncertain how class I molecules are targeted to endosomal compartments. Several class I allomorphs have been reported to associate with the invariant chain (Cerundolo et al. 1992), and the invariant chain has been reported to direct HLA-B27 to endosomal compartments (Sugita and Brenner 1995). The trafficking of class I molecules from endosomes to the plasma membrane of DCs is upregulated upon DC maturation (MacAry et al. 2001). The mechanism underlying this and nearly every aspect of the intracellular trafficking of class I molecules to and from endosomes remains to be characterized.

Class I molecules are also present in exosomes: small vesicles generated in the lumen of large endosomes by a pinching-off process with the topological consequence of orienting luminal domains of integral membrane proteins (similar to class I molecules) on the outer surface of the exosome. After the fusion of multivesicular endosomes with the plasma membrane, exosomes are released by cells. Originally described in reticulocytes, exosomes are also known to be produced by B cells and DCs. Exosomes are rich in MHC class II and co-stimulatory molecules, and are able to able to stimulate $CD4^+$ (Raposo et al. 1996) and $CD8^+$ T cells (Zitvogel et al. 1998). The physiological significance of exosomes in immune responses remains to be established.

ANTIGEN PROCESSING IN ENDOSOMAL COMPARTMENTS

The possibility of endosomal processing of MHC class I antigens was first shown using antigen coupled to beads (Rock et al. 1990), and has now been extended to a large number of antigens, including bacteria, viruses, virus-like particles, and aggregated proteins (reviewed in Yewdell et al. 1999b). Although 'peptide regurgitation' (i.e. cell-surface PR class I binding of peptides generated in endosomal compartments) (Pfeifer et al. 1993) has been shown to occur under some conditions, it is likely that peptides generated in endosomes bind to endosomal class I molecules. Although every cell type is probably capable of endosomal processing, it occurs more efficiently in pAPCs. The extent to which this is caused by the increased endocytosis versus enhanced trafficking of class I molecules to and from endosomes versus enhanced peptide generation versus facilitated loading remains to be established. Indeed, precious little is known about endosomal processing of class I peptides, and the nature of the proteases and mechanism of peptide loading are completely undefined.

WHAT DO MOLECULAR CHAPERONES DO?

In searching for factors that are able to prime the immune system to reject transplanted tumors, Srivastava and colleagues discovered that the molecular chaperone gp96 purified from tumor cells is able to induce protective immunity against tumor challenge (Li et al. 2002). These findings have been extended to show that several different molecular chaperones are able to induce $CD8^+$ T-cell responses to defined antigens when the chaperones are purified from cells expressing the antigen or loaded with antigenic peptides (Li et al. 2002). Notably, the responses induced by molecular chaperones are quite weak in comparison to virus infections, and even to other exogenous antigen preparations. The jury is still out on the physiological role of molecular chaperones in the crosspriming phenomenon (Wallin et al. 2002), though recent evidence disfavors their participation in crosspriming (Norbury et al. 2004; Wolkers et al. 2004).

INTRODUCTION

CD8 T cells are a subset of T lymphocytes that are responsible for cellular immune responses. CD8 T cells recognize specific peptide epitopes presented by class I major histocompatibility complexes (MHC) on the surface of pathogen-infected or malignant cells using T-cell receptors (TCR) and CD8 molecules. TCRs consist of α and β chains, which associate with CD3 molecules. TCRs associating with CD3 bind to peptide and the polymorphic region of MHC, whereas CD8 binds to the nonpolymorphic region. After recognition of peptide–MHCI complexes and binding to several adhesion molecules on pathogen-infected and malignant cells, CD8 T cells are able to protect against pathogens and malignancies by secreting soluble mediators and inducing cytotoxicity. In this chapter, the role of CD8 T cells in the control of infectious diseases and malignancies, the induction of CD8 T-cell responses, and the protective mechanisms mediated by CD8 T cells are discussed.

CD8 T LYMPHOCYTES IN THE CONTROL OF INFECTIOUS DISEASES

CD8 T-cell immunity to viruses

Unlike extracellular pathogens, viruses are obligate intracellular pathogens, the multiplication of which occurs inside infected cells; once released from infected cells, mature virions will infect other normal cells. Although virus-specific antibodies can clear extracellular virus particles by neutralization or other mechanisms, antibodies may not be able to effectively eliminate intracellular virus, particularly as some viruses can be transmitted by fusion between infected and normal cells (Spickett et al. 1989; Rausch et al. 1992; Kahn et al. 1999). When virus infection occurs, viral antigens are processed into short peptides, which are presented by MHCI molecules (Townsend and Bodmer 1989), CD8 T cells are able to recognize these peptide epitopes presented by MHCI molecules. The level of CD8 T-cell responses also increases earlier than that of other adaptive immune responses. The level of CD8 cytotoxic T-lymphocyte (CTL) activity can be measured by in vitro cytotoxicity assays or cytokine analysis. After recognition of peptide–MHC complexes presented by virus-infected cells, CD8 CTLs are capable of inhibiting intracellular virus proliferation by cytotoxicity or the activity of secreted cytokines (Guidotti and Chisari 2001). Virus-specific CD8 CTL responses induced by different vaccine constructs have been demonstrated to protect against several virus infections in animal models (Schulz et al. 1991; Ciernik et al. 1996; Hsu et al. 1998, 1999; Leifert et al. 2001; Li et al. 2001a; Nass et al. 2001; Gierynska et al. 2002). Whether or not the level of CTL activity or the frequency of CD8 CTLs is important in

conferring protection needs further investigation in situations where protective immune responses have been induced after immunization.

Different viruses also have a variety of ways to escape CD8 T-cell responses (Phillips et al. 1991; Goulder et al. 1997; McMichael and Phillips 1997; McMichael and Rowland-Jones 2001), which could result in persistence of virus infection or reinfection within the population. Viruses with a potentially high mutation rate, such as human immunodeficiency virus (HIV), simian immunodeficiency virus (SIV), hepatitis C virus (HCV), and influenza virus with antigenic variations within the epitopes, are able to avoid CTL recognition. These observations demonstrate the protective role of CD8 CTLs (Price et al. 2000; Erickson et al. 2001; McMichael and Rowland-Jones 2001). Herpesviruses can interfere with the MHCI processing and presentation pathway (Yamashita et al. 1993; Hill et al. 1995) and respiratory syncytial virus infection can suppress CD8 T-cell memory responses (Chang and Braciale 2002). HIV, adenovirus, and cytomegalovirus (CMV) can down-regulate MHCI molecule expression on the cell surface (Yamashita et al. 1993; Pereira et al. 1995; Mahr and Gooding 1999; Reusch et al. 1999; McMichael and Rowland-Jones 2001). However, little is known about the dynamics of immune responses after infection with mutant viruses. Specificity, cytokine expression and frequency of CD8 T-cell responses to wild-type viruses may be different from those to mutant viruses during infection. The results of studies of the differences in CD8 T-cell responses after infection with wild-type virus and mutant virus could help in the design of promising and effective vaccine constructs and new immunization strategies.

CD8 T-cell immunity to bacteria

Most pathogenic bacteria can survive and proliferate outside cells. However, when intracellular bacteria, such as mycobacteria and *Listeria* spp., cause infection, CD8 T cells could play an important protective role (Gellin and Broome 1989; Harty et al. 1992; Clemens and Horwitz 1996; Sturgill-Koszycki et al. 1996). Mycobacteria are acid-fast intracellular pathogens and, after infection, they can survive in certain endosomal compartments (Sturgill-Koszycki et al. 1996). Mycobacterial antigens are processed in these compartments into peptide fragments that are presented by MHCI molecules to CD8 T cells. Both αβ- and γδ T cells have been shown to play a protective role against mycobacterial infections (Ladel et al. 1995; D'Souza et al. 1997). CD8 CTLs can mediate protective immunity against mycobacteria by granule-mediated cytolysis or by the release of cytokines, such as interferon-γ (IFN-γ) (Harty et al. 1992; Ehrt et al. 2001). IFN-γ and interleukin-12 (IL-12) are also involved in granulomatosis and the generation of protective cellular immune responses (Cooper et al. 1997). Protective CD8 CTL responses against mycobacteria can be induced by a variety of vaccine preparations, including recombinant viral vaccines and DNA vaccines (Lowrie et al. 1997; Zhu et al. 1997).

Listeria monocytogenes is a gram-positive intracellular bacterium that causes listeriosis (Gellin and Broome 1989). Infection with live *L. monocytogenes* induces antigen-specific CD8 T-cell responses, with peak responses 7–9 days and 5 days after reinfection (Busch et al. 1998). Antigen-specific CD8 T-cell responses induced by live *L. monocytogenes* provides protective immunity against subsequent infection. On the other hand, immunization with heat-inactivated *L. monocytogenes* could not provide effective protection against subsequent infections, although the size of the antigen-specific CD8 T-cell population was increased to the same extent as that in immune animals (Von Koenig et al. 1982; Lauvau et al. 2001). However, in situations where CD8 T-cell responses did confer protective immunity against intracellular bacteria after infection or immunization, the soluble mediators secreted by CD8 T cells participating in protection still remain unknown.

CD8 T-cell immunity to parasites

Most pathogenic parasites have complicated life cycles with different developmental stages (Markell and Voge 1981). After infection with intracellular parasites, parasitic antigens are processed and presented as MHCI–peptide complexes in infected cells, which are recognized by CD8 T cells at certain stages in some cases. Thus, CD8 T cells are able to protect against malaria infection at the liver stages (Hoffman et al. 1989; Romero et al. 1989; Charest et al. 2000). Antigen-specific CD8 T-cell responses protect against *Toxoplasma gondii* parasites after immunization (Khan et al. 1994; Nielsen et al. 1991, 1999). In CD8-deficient or CD8-depleted animals, the growth of leishmania parasites cannot be controlled, which indicates the protective role of CD8 T cells in this infection (Belkaid et al. 2002). The protective ability of CD8 T cells against a variety of parasitic infections has also been demonstrated by the adoptive transfer of parasite-specific CD8 T cells from immune animals (Nielsen et al. 1991). As a result of their complicated life cycles, many parasitic antigens from parasites are expressed in different stages and, as an added complication, malaria parasites can also infect red blood cells, which are cells that do not express MHCI–peptide complexes (Urban et al. 1999). The question of whether there are malaria antigens expressed in red blood cells capable of regulating CD8 T-cell responses has yet to be answered.

Parasites have also developed different ways of escaping immune responses (Borst 1991; Hall and Joiner 1991; Barral-Netto et al. 1992), including antigenic variation, modulation of cytokine expression, avoidance of

killing by oxygen metabolites or hydrolase, and alteration of the function of antigen-presenting cells (APC). Whether certain parasites have also developed the same strategies as used by viruses to escape CD8 T-cell responses remains to be investigated.

CD8 T LYMPHOCYTES IN THE CONTROL OF MALIGNANCIES

CD8 T-cell immunity to tumors

Historically, several lines of evidence have shown the existence of tumor-specific immunity. Clinical evidence has also shown that tumors sometimes regressed in cancer patients after bacterial infection and the growth of tumors is suppressed after transplantation into an MHC-incompatible host in experimental models. The immune surveillance hypothesis was proposed to explain the role of immune responses in the control of tumors (Boon et al. 1994). Although immune responses are able to control tumors, they always eventually escape immune attack in the absence of the use of further and better treatment (Marincola et al. 2000). In contrast to MHCII molecules, which are mainly expressed on specialized APCs, most cells express MHCI molecules, including tumor cells. With their ability to recognize specific peptide–MHC complexes, CD8 CTLs are considered to be important effectors of cellular immunity against tumor cells. To induce specific CD8 CTL responses against tumor cells, the identification of tumor antigens is important and this also has importance for the development of immunotherapeutic approaches. Several tumor antigens have been identified that have the ability to induce protective tumor-specific CD8 CTL responses, e.g. the melanoma antigens, MAGE, BAGE, and GAGE, are expressed in melanoma cells but not in normal cells (Boon et al. 1994). Many of the melanoma-associated antigens are derived from normal nonmutated melanocyte differentiation antigens, including MART-1, gp-100, and tyrosine-related protein-2 (Zeh et al. 1999).

The lack of appropriate tumor antigens has impeded the development of effective immunotherapeutic approaches to other tumors. To induce protective CD8 T-cell immunity to other tumors, tumor-associated antigens that are overexpressed selfantigens in other tumors, such as mdm and WT-1, have been used in attempts to generate protective tumor immunity (Sadovinikova and Stauss 1996; Gao et al. 2000; Ohminami et al. 2000; Oka et al. 2000). As these overexpressed tumor antigens are expressed in normal cells at lower levels, there is a possibility that deleterious autoimmune responses could be induced when effective tumor-specific T-cell responses are generated against them. Furthermore, the induction of tolerance could also impair the maintenance of T-cell responses against tumors using these overexpressed self-proteins as tumor antigens.

Tumor immunotherapy by CD8 T cells

Tumor immunotherapy can provide an alternative method to traditional therapeutic approaches. Several immunotherapeutic approaches have been developed to generate humoral or cellular immunity to tumors, including the induction of protective cellular immune responses by immunization with tumor antigens and the generation of tumor-specific CTL lines or clones with APCs expressing tumor antigens (Matis et al. 1986). Different tumor antigen preparations have been developed for immunization purposes (Oka et al. 2000). Tumor antigens formulated in different adjuvants, expressed in viral vectors or nucleic acids, and expressed in specialized APCs have been used to induce tumor-specific CD8 CTL responses (Ciernik et al. 1996). CD8 CTL peptide epitopes identified from tumor antigens have been used to generate CD8 CTL lines or clones for tumor immunotherapy (Sadovinikova and Stauss 1996; Zeh et al. 1999). CD8 CTL epitopes have also been used for the construction of vaccines to generate protective CD8 CTL responses. Several vaccine preparations and immunization approaches, including the induction of CD4 T-cell responses and the inclusion of cytokines, chemokines, and costimulatory molecules in the vaccine design, have been used to improve the effectiveness of tumor-specific CD8 CTL responses. In animal models, the induction of tumor-specific CD8 CTL responses by immunization and the transfer of tumor-specific CTL lines or clones have had some success in the control of tumor growth, although the control of growth was not complete. Variations in the effectiveness of immunotherapy to different tumors using CD8 T cells have also been described. Similar to pathogens in some aspects, tumors are also able to avoid immune responses by modulating the expression of MHC molecules, cell surface molecules, and cytokines (Marincola et al. 2000; Buggins et al. 2001; Ibrahim et al. 2001). The investigation of the mechanisms used by specific cells to evade immune responses could lead to the design of better therapeutic strategies. However, the mechanisms used by CD8 CTL to control tumor cells are also not clear other than their cytolytic activity and cytokine expression.

THE PROTECTIVE MECHANISMS INVOLVING CD8 T LYMPHOCYTES

Soluble mediators secreted by CD8 T cells

CD8 T cells protect against infection by intracellular pathogens via cytolytic and noncytolytic mechanisms (Barth et al. 1991; Tuttle et al. 1993; Yang and Walker 1997; Guidotti and Chisari 2001; Binder and Griffin 2001; Russell and Ley 2002). The noncytolytic mechanisms are mediated by cytokines, chemokines, and other

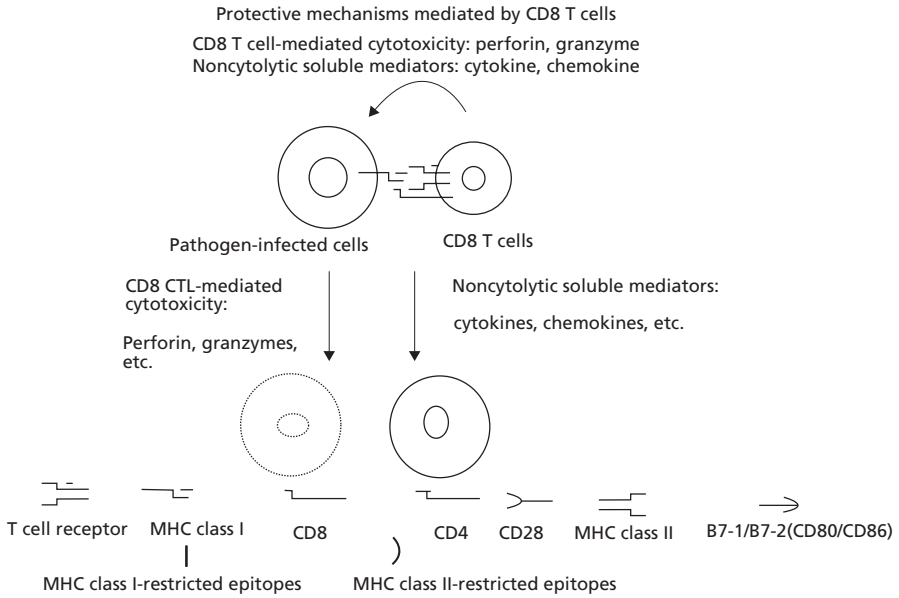

Figure 1 *CD8 T cells can protect against pathogens by secreted noncytolytic soluble mediators or granule-mediated cytolysis. Noncytolytic soluble mediators include cytokines or chemokines that inhibit proliferation or infection of intracellular pathogens. Granules containing perforins, granzymes, etc. induce cytolysis of pathogen-infected cells. CTL, cytotoxic T lymphocyte.*

soluble mediators secreted from CD8 T cells (Figure 1). The involvement of these noncytolytic mechanisms in protection against pathogens was observed in experiments by using particular cytokine gene-deficient animals or depletion of particular cytokines by a specific antibody in animal models (Klavinskis et al. 1989; Tishon et al. 1995; Hsu et al. 1998). Using these approaches, it has been shown that certain cytokine-deficient CD8 T cells are less efficient in the control of infection with some pathogens than with others (Harty et al. 1992; Tishon et al. 1995). CD8 T cells secrete several antiviral cytokines after infection or peptide epitope stimulation (Klavinskis et al. 1989; Hsu et al. 1998; Patterson et al. 2002). IFN-γ and tumor necrosis factor α (TNF-α) secreted by CD8 T cells are able to reduce virus infection by intracellular or extracellular mechanisms, to recruit and activate macrophages, T cells, or natural killer (NK) cells to perform their effector function. IFN can directly inhibit virus replication by activating the oligoadenylate synthetases, Mx proteins, double-stranded-RNA-activated protein kinase, and the double-stranded-RNA-specific adenosine deaminase systems (Silverman 1994; Patterson et al. 1995; Haller et al. 1998; Terenzi et al. 1999). Oligoadenylate synthetases suppress viral replication by induction of several cellular RNases that degrade viral transcripts. Double-stranded-RNA-activated protein kinase and adenosine deaminase inhibit viral protein synthesis. IFN-γ and TNF-α are also able to regulate antigen processing and presentation, enhance the expression of MHC molecules on the cell surface, and recruit macrophages, NK cells, and T cells into virus infection sites to perform their antipathogen effector function.

During pathogen infection, CD8 T cells are capable of making and secreting many cytokines, chemokines, and other soluble mediators with as yet unknown functions (Toso et al. 1995; Wagner et al. 1998). Anti-HIV-specific CD8 T cells can produce unidentified noncytolytic factors that suppress HIV viral replication in vitro after antigen recognition (Toso et al. 1995). Intracellular bacteria and parasites are also inhibited by several cytokines secreted from CD8 T cells. The detailed intracellular events that inhibit intracellular bacteria or parasites are less clear than those that inhibit intracellular viruses. Although the intracellular mechanisms that inhibit viral replication have been well studied, there are still intracellular events that are not very clear other than the suppression of viral RNA or protein synthesis. The induction of the expression by intracellular molecules, which play an important role in the inhibition of intracellular bacteria and parasites, has been suggested by several authors (Seguin et al. 1994; Scheller et al. 1997). Further investigation of the intracellular events that protect against infection of intracellular bacteria, parasites, or viruses by cytokines could lead to the design of effective therapeutic approaches. Whether there are unidentified soluble molecules produced by CD8 T cells that protect against different virus infections represents a new area to be explored.

CD8 T-cell-mediated cytotoxicity

CD8 CTLs can mediate cytolysis of pathogen-infected or malignant cells by granule exocytosis of perforin, granzymes, and other molecules (Russell and Ley 2002). CD8 CTLs are also able to lyse the pathogen-infected or

malignant cells by the Fas/Fas ligand pathway (Figure 1). After T-cell activation, granules including perforin, granzyme, and other components are synthesized and reside in the cytoplasm. In the recognition of pathogen-infected cells, granules are fused with cell membranes at the contact sites of the tight junction between CD8 T cells and target cells. Once granules are released from CD8 T cells, perforin polymerizes to insert into the cell membrane and induces membrane damage in the presence of calcium (Tschopp et al. 1989; Muller and Tschopp 1994). Although the function of perforin is similar to that of complement in inducing membrane damage, perforin alone is not sufficient to induce apoptosis of the target cells. Perforin alone was thought to be capable of causing apoptosis of the target cells; however, several authors have suggested that the pore created by perforin is too small to allow large molecules, granzymes, and other components to pass into the target cells to induce apoptosis (Podack et al. 1985; Browne et al. 1999). This debate does not change the fact that the function of perforin is to induce membrane damage. However, the role of perforin in cytotoxicity mechanisms induced by granule exocytosis remains to be defined.

Granzymes are serine proteases in the cytotoxic granules: granzyme A is the tryptase that prefers to cleave protein substrates in the position of arginine or lysine residues (Odake et al. 1991). Granzyme B is similar to the capases that prefer to cleave protein substrates in the position after aspartic acid residues (Odake et al. 1991). The function of granzyme A and other granzymes in cytotoxic granules has not been defined. Granzyme B cleaves procapase-3 and other procaspases in vitro (Sarin et al. 1998; Yang et al. 1998; Sutton et al. 2000), which could also be required for activation of caspase-3 to cleave other substrates in the target cells. After granule exocytosis by CD8 CTL, the cascade effect of substrate digestion by granzymes could result in apoptosis of target cells. Granzyme B induces nuclear DNA fragmentation in cells that are functionally caspase deficient, which suggests that this enzyme can directly activate apoptotic nucleases (Sutton et al. 2000). One of the apoptotic nucleases was identified as caspase-activated DNase (Enari et al. 1998). Granzyme B can enter the nucleus without the involvement of perforin or the alteration of the nuclear pore (Jans et al. 1996). In one of the pathways of granzyme-induced apoptosis, the involvement of mitochondria has been suggested because Bcl-2 can block death induced by perforin and granzymes (Russell and Ley 2002).

Granzyme A is less efficient at inducing apoptosis than granzyme B and the cellular pathways used by granzyme A to induce apoptosis are different from those by granzyme B. Granzyme A neither activates caspases nor induces cleavage of granzyme B substrates, caspase-3, DNA-dependent protein kinase (DNA-PK), or Poly-ADP-ribose-polymerase (PARP). Granzyme A does not result in oligonucleosomal DNA degradation, but only induces single DNA breaks, indicating that granzyme A activates different nucleases from those activated by granzyme B (Shi et al. 1992). The mechanisms used by CD8 CTLs to avoid cell death after granule exocytosis have been studied for many years and CD8 CTLs contain an inhibitor of granzyme, B, known as protease inhibitor 9 (PI-9) (Sun et al. 2001). When murine homologues of this inhibitor, SPI-6 and PI-9 are overexpressed in target cells, they protect these cells from death (Medema et al. 2001). The detailed mechanisms of the intracellular cascade events resulting in the induction of apoptosis of target cells are still unclear. Several viruses can encode inhibitors of granzyme B to inhibit both Fas- and granzyme-mediated lysis, including the poxvirus-encoded cytokine response modifier A (CrmA) and the granzyme B inhibitor which interacts with granzyme B and several capases to inhibit CTL-mediated lysis (Tewari et al. 1995). A study of the mechanisms used by viruses or tumor cells to evade CTL-mediated lysis by granzymes may well provide information that could help in the design of better immunization and therapeutic approaches.

THE DEVELOPMENT OF VACCINES FOR THE INDUCTION OF CD8 T-CELL RESPONSES

Inactivated vaccines

For many years, inactivated vaccines have been prepared from whole virions treated with chemicals, such as formalin, that reduce their infectivity and maintain their ability to stimulate protective immunity (Eller 1969; Fulginiti et al. 1969; Kapikian et al. 1969; Kim et al. 1969). Inactivated pathogens are the only vaccines available to stimulate protective antibody responses for many diseases. Although inactivated vaccines were thought to maintain the immunogenicity to stimulate immune responses with minor damage to the structure of viral proteins, formalin-inactivated vaccines are ineffective at generating protective, conformation-dependent, antibody responses and cellular immune responses mediated by CD8 CTLs (Chargelegue et al. 1998; Hsu et al. 1999). There are also other disadvantages of inactivated vaccines: virulent pathogens could still be infectious if the quality of vaccine preparation is not well controlled; and the contamination of vaccine preparations with materials derived from tissue culture could result in hypersensitivity reactions (Eller 1969; Chanock et al. 1992; Wertz and Sullender 1992). Indeed, the use of formalin-inactivated respiratory syncytial virus vaccines induced exacerbated disease during a subsequent epidemic (Fulginiti et al. 1969) and the pathological effects induced by formalin-inactivated respiratory syncytial virus vaccine have been extensively studied

(Openshaw et al. 2001). A detailed analysis of the factors that result in pathological consequences following the use of formalin-inactivated vaccines is important for the development of new vaccines and immunization strategies to generate protective immunity without exacerbated diseases.

Attenuated vaccines

Attenuated vaccines are mutant live pathogens that have similar antigenicity to wild-type pathogens and induce no pathogenic effects (Wegmann et al. 1986). Mutant live pathogens are selected by attenuating strains of wild-type pathogens in serial cell culture or by genetic manipulation (Beck et al. 1986; Wertz and Sullender 1992; Khattar et al. 2001; Bukreyev et al. 1999, 2001; Stittelaar et al. 2002). Many of the currently available vaccines to prevent infectious diseases are live attenuated vaccines (Table 1) that are considered to induce protective humoral and cellular immune responses similar to those induced by the wild-type virus but without pathogenic consequences. In contrast to inactivated vaccines, live attenuated vaccines are able to induce pathogen-specific CD8 CTL responses. There is very little information about the differences in cellular immune responses mediated by CD8 CTL responses generated by attenuated vaccines and wild-type pathogens, and a comparison of these differences will facilitate the development of better vaccines and immunization approaches to avoid any pathogenic consequences of immunization.

Genetic manipulation approaches can be used to insert foreign genes with immunoregulatory functions, such as cytokines, into the pathogen genome, to delete the genes related to pathogenic effects, to introduce mutations into the genome of pathogens to enhance protective immunity, and to avoid exacerbated pathogenesis (Bukreyev et al. 1999, 2001; Khattar et al. 2001). Although the attenuated vaccines currently in use have given encouraging results in conferring protective immune responses against many infectious diseases, there is an urgent need to develop alternative vaccines to prevent infection with mutant pathogens. There is a possibility that attenuated vaccines may revert to the virulent strain or could be contaminated with virulent pathogens after serial cultivation in tissue culture or in the infected population. Investigations into the long-term pathogenic effects of immunization with attenuated vaccines will be important for the design of improved vaccines.

Subunit vaccines

Subunit vaccines mainly comprise protein or carbohydrates expressed by pathogens that are recognized by antibodies, T lymphocytes, or other immune cells (Zuckerman 1986; Jones et al. 1996; Lingappa et al. 2001). Many viral proteins expressed on the surface of virions have been selected as subunit vaccines for the induction of protective antibody responses (Zuckerman 1986; Schirmbeck et al. 1994; Li et al. 1998; Bembridge et al. 2000). Surface and internal virus proteins are capable of generating protective T-cell responses (Schirmbeck et al. 1994; Li et al. 1998; Bembridge et al. 2000). Although capsular carbohydrate antigens are used as subunit vaccines to generate immune responses (Jones et al. 1996; Lingappa et al. 2001), they are not effective at generating antibody responses without the inclusion of a protein carrier or appropriate adjuvant formulations. Designing appropriate immunization strategies and vaccine constructs to generate anticarbohydrate immune responses is important for the development of vaccines against pathogenic bacteria with capsular carbohydrate antigens. T-cell recognition of carbohydrates has also been suggested by several authors (Carbone and Gleeson 1997; Galli-Stampino et al. 1997; Deck et al. 1999; Haurum et al. 1999), and that MHCI molecules present glycopeptides to CD8 T cells. Immunization with MHC-restricted binding glycopeptides generates

Table 1 *Vaccines in use to prevent infectious diseases*

Prevention of infectious diseases	Vaccines in use	Route of immunization	CD8 CTL induction
Poliomyelitis	Live attenuated	Oral	Yes (++++)
MMR			
Measles	Live attenuated	Parenteral	Yes (++++)
Mumps	Live attenuated	Parenteral	Yes (++++)
Rubella	Live attenuated	Parenteral	Yes (++++)
Hepatitis B	Subunit vaccines	Intramuscular	(–)?
Purified HBsAg from healthy carrier			
HBsAg from recombinant DNA in yeast			
Haemophilus influenzae b	Subunit vaccines		(–)?
Capsular carbohydrate conjugate vaccine			
Meningococcal C	Subunit vaccines		(–)?
Capsular carbohydrate conjugate vaccine			

(++++), vaccines are efficient at induction of CD8 CTL responses. (–)?, considered to be inefficient at inducing CD8 CTL responses. The ability of the vaccines (hepatitis B subunit vaccines) to induce CD8 CTL responses is not conclusive in the literature. HBsAg, hepatitis B surface antigen.

glycopeptide-specific, MHC-restricted, CD8 CTLs (Speir et al. 1999); however, the function of glycopeptide-specific CD8 T cells in the control of infection with pathogens expressing carbohydrates is not completely understood.

Advances in molecular biology have facilitated the development of subunit vaccines in which the proteins of pathogens are purified as protein subunit vaccines, expressed with other proteins as fusion protein subunit vaccines, or inserted into a variety of vectors as recombinant subunit vaccines (Gherardi et al. 1999; Berzofsky et al. 2001). However, immunization with purified soluble proteins from pathogens is not effective at inducing CD8 T-cell responses in the absence of appropriate adjuvant formulation (Schirmbeck et al. 1994; Speidel et al. 1997; Sheikh et al. 1999). The use of some subunit proteins has resulted in the induction of exacerbated disease after infection.

Priming with G protein derived from respiratory syncytial virus resulted in eosinophilia during subsequent infection (Openshaw et al. 1992). Although different genetic, physical, or chemical modifications of purified

proteins have been used to improve humoral and cellular immune responses after immunization, these approaches have tended to enhance one arm of immune responses while inhibiting the other (Speidel et al. 1997). Whether antigen processing and presentation of fusion protein vaccines are similar to those of protein antigens expressed on pathogens is not clear. The conformation of epitopes of fusion proteins may also be different from that of protein antigens expressed on pathogens. Pathogen proteins are inserted and expressed in different vectors, including viral, bacterial, and plasmid DNA vectors, as recombinant subunit vaccines. Recombinant subunit vaccines using live viral or bacterial vectors have the disadvantage that the boosting is ineffective because immune responses could be directed to the vectors rather than to the expressed pathogen proteins (Fuller et al. 2002; Harrington et al. 2002). Mutant pathogens with antigenic variations could also escape from the immune responses generated by recombinant vaccines expressing proteins from wild-type pathogens.

Epitope-based vaccines

Epitopes are small fragments of antigens that are recognized by specific antibodies produced from B lymphocytes (B-cell epitopes) or presented by MHC to TCRs of T lymphocytes (T-cell epitopes). Most epitopes are peptides derived from proteins of pathogens or specific antigens. CD8 T-cell peptide epitopes consist of 8–12 amino acids that bind to MHCI molecules (Townsend et al. 1989). Epitope-based vaccines consist of T- or B-cell epitopes that are made as synthetic peptides or synthetic oligonucleotides expressed by plasmid DNA or a variety of recombinant vectors (Chargelegue et al. 1998; Hsu et al. 1998, 1999; Berzofsky et al. 2001; Wee et al. 2002). Synthetic peptides, epitope-based DNA, or recombinant vectors expressing T-cell epitopes have all been shown to be capable of inducing protective CD8 CTL responses.

Synthetic peptides alone are often not able to induce effective immune responses without modification by the inclusion of additional sequences or the use of specific adjuvant formulations. Several sequence modifications and different adjuvants have been applied to the enhancement of induction of CD8 CTL responses (Gao et al. 1991; Hsu et al. 1995; Franke et al. 1997). Thus, the addition of T-helper epitopes, fusion peptide, lipophilic molecules, and signal peptides to CD8 CTL epitopes has resulted in enhanced specific CD8 CTL responses (Shirai et al. 1994; Hsu et al. 1995; Hiranuma et al. 1999). One of the advantages of the use of epitope-based vaccines is to allow T-cell epitopes to bind to MHC molecules bypassing some of the steps in protein antigen processing and presentation pathways. The flexibility of the design of epitope-based vaccines also allows peptide epitopes to be delivered to particular intracellular organelles to activate specific protective immune responses. Epitope-based immunization strategies could also be used to explore several unclear areas in immunology at the intercellular level, such as the extent of the TCR repertoire, the importance of the affinity–avidity of T-cell recognition, and the role of CD4–CD8 and CD8–APC interactions. The information from these areas can aid the design of a new generation of epitope-based vaccines and immunization strategies.

THE INDUCTION OF CD8 T-CELL RESPONSES

The role of CD4 T cells

In contrast to CD8 T cells, CD4 T cells recognize peptide epitopes bound to MHCII molecules presented by specialized APCs, such as dendritic cells or macrophages (Allen et al. 1985). CD4 T cells are able to improve CD8 T-cell immunity against pathogens and malignant cells after infection or immunization (Berzofsky et al. 2001); however, the mechanisms used by CD4 T cells to increase CD8 T-cell activity are not clear. CD4 T cells could simply expand the frequency of CD8 T cells or alter the function of CD8 T cells and vice versa. Indeed, CD8 T-cell responses can be expanded or suppressed via the action of cytokines or other soluble mediators from different types of CD4 T cells (Aung and Graham 2000; Aung et al. 1999; Sato et al. 2001). Specialized APCs express MHCI and MHCII molecules that are capable of presenting peptide epitopes to CD4 and CD8 T cells (Figure 3). CD8 T-cell responses could also be augmented by the microenviroments of cell–cell contacts between CD8 T cells, CD4 T cells, and specialized APCs. Induction of protective CD8 T-cell immunity by specialized APCs in the absence of CD4 T-cell responses has also been described (Sato et al. 2001; Wang et al. 2001; Diehl et al. 2002). Different vaccine preparations have been used to induce specific CD8 T-cell responses and, in many cases, vaccines including components for the induction of CD4 T-cell responses have resulted in enhanced specific CD8 CTL responses. It should be noted that CD8 CTL responses could also be induced in the absence of CD4 T-cell responses (Figure 3). The induction of CD8 T-cell responses with peptides bound with higher affinity to MHCI molecules depends less on the presence of exogenous CD4 T-cell peptide epitopes than CD8 epitopes bound with lower affinity to MHCI molecules. Whether or not other factors contribute to the induction of effective CD8 T-cell immunity by specialized APCs without CD4 T cells needs further investigation.

The role of antigen-presenting cells

CD8 T cells can recognize APCs expressing MHCI–peptide molecules on the cell surface. Several APCs,

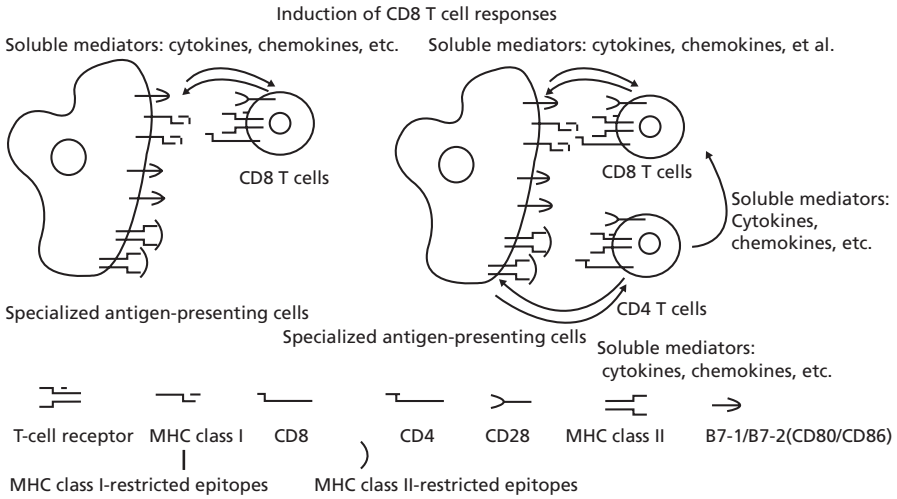

Figure 3 *Specialized antigen-presenting cells (APC) present MHCI- and MHCII-restricted epitopes to CD8 and CD4 T cells. CD8 T-cell responses are induced by cell-to-cell contact of CD4, CD8, and specialized APCs upon costimulatory signals or be soluble mediators, CD8 T-cell responses are also capable of being induced in the absence of CD4 T cells.*

such as fibroblasts, epithelial cells, endothelial cells, and different specific cells, are recognized and lysed by CD8 CTLs in vitro using CTL assays (Bennink et al. 1982; Gooding and O'Connell 1983; Townsend et al. 1986; Li et al. 2001b). MHCI-restricted antigen processing and presentation by specialized APCs, such as dendritic cells or macrophages, is required to induce and activate CD8 T-cell responses, as indicated in many publications. In these studies, several different ways to prepare and purify dendritic cells were used to induce protective CD8 T-cell responses (Steinman 1991; Galibert et al. 2001; Manz et al. 2001). There is limited information available to determine whether variations in methods for generation and purification of dendritic cells could alter their immunological function.

Specialized APCs, which some pathogens can directly infect, are capable of presenting MHC–peptide complexes to CD8 T cells through the endogenous MHCI processing and presentation pathway (Bennink et al. 1982; Townsend et al. 1986, 1989; Moore et al. 1988; Pamer and Cresswell 1998; Rock and Goldberg 1999). For other pathogens and particulate antigens, specialized APCs could present MHCI–peptide complexes to CD8 T cells via exogenous pathways that normally present MHCII–peptide complexes to CD4 T cells (Yewdell et al. 1988; Schirmbeck et al. 1995; Rock and Goldberg 1999; Pamer and Creswell 1998; Rock and Goldberg 1999; Stober et al. 2002). In classic MHCI endogenous antigen processing pathways, cytoplasmic antigens are processed into peptides by ubiquitin- and proteosome-mediated proteolysis (Rock et al. 1994; Rock and Goldberg 1999). Processed peptides are transported into the endoplasmic reticulum by TAP-dependent or TAP-independent pathways. After peptide epitopes are selected and bound to MHCI molecules, MHCI–peptide molecules are transported to the Golgi body and then to the cell surface. In the alternate exogenous MHCI pathway, exogenous antigens are endocytosed by specialized APCs into endosomal compartments. Protein antigens are processed by endosomal proteases into peptide fragments and processed peptides are transported into the cytoplasm to enter the endoplasmic reticulum or into other organelle compartments to associate with MHCI molecules. The detailed intracellular pathways of MHCI molecules are not totally clear, and whether the peptide repertoires produced by classic endogenous pathways are different from those produced by alternate exogenous pathways is not known. Specialized APCs stimulate effective specific CD8 CTL responses against pathogens or tumors, when pulsed with peptides and particulate protein antigens or by transfection with recombinant vectors in vivo or in vitro (Porgador and Gilboa 1995; Schirmbeck et al. 1995; Luft et al. 2002; Stober et al. 2002). Specialized APCs are able to express MHCI, MHCII, costimulatory, and other surface molecules. A knowledge of the differences in expression of surface molecules and cytokines between specialized APCs and other APCs is required in order to regulate the immunostimulatory function of specialized APCs for immunotherapy and the generation of protective immunity.

The role of cytokines

Several cytokines are involved in the induction of CD8 T-cell responses after pathogen infection or immunization. Many cytokines have already been included in the design of vaccines and adjuvant formulations to enhance the induction of CD8 CTL responses (Ahlers et al. 2001; Sato et al. 2001; Staats et al. 2001; Cho et al. 2002; Luft et al. 2002; Padovan et al. 2002). Some cytokines, such as interleukin 2 (IL-2), directly stimulate CD8 T-cell proliferation and activation. Granulocyte–monocyte

colony-stimulating factor (GM-CSF) and IL-12 are able to upregulate the expression of receptors or surface molecules on CD8 T cells, to induce T-helper cell responses or to induce the cascade effects of cytokine expression from other cells (Gerrard et al. 1987; Ahlers et al. 2001; Berzofsky et al. 2001). IL-12 is able to enhance the induction of CD8 CTL responses and the production of IFN-γ Gately et al. 1994) and GM-CSF increases the number of infiltrating APCs and enhances the expression of IFN-γ and IL-12 receptors (Ahlers et al. 2001; Bukreyev et al. 2001). In addition, cytokines can also act synergistically on the induction of CD8 T cell responses (Mehrotra et al. 1995; Ahlers et al. 2001; Berzofsky et al. 2001). Type 1 IFNs are required for bone marrow- or resident monocyte-derived dendritic cells to stimulate CD8 CTL responses (Palmer et al. 2000; Luft et al. 2002; Montoya et al. 2002; Padovan et al. 2002). Both type 1 and type 2 IFNs regulate MHCI-restricted antigen processing and presentation (Atta et al. 1995; Keskinen et al. 1997). IL-4 has been found to suppress or enhance CD8 CTL activity in different experimental conditions (Bembridge et al. 1998; Aung et al. 1999; Aung and Graham 2000). Finally, cytokines are also involved in pathogenesis of diseases after pathogen infection (Peebles et al. 2000; Openshaw 2002).

Whether cytokines enhance the induction of CD8 CTL responses through the regulation of antigen processing and presentation is an important area to be explored. In several publications, a significant effect on immune responses was observed in the situation of IFN-γ deficiency, which is consistent with the observation that IFN-γ has an effect on the antigen processing and presentation pathway (Hsu et al. 1998; Guidotti and Chisari 2001; Nakajima et al. 2001), and induces the expression of subunits of proteasomes that are responsible for proteolysis in the MHCI-processing pathway (York and Rock 1996; Pamer and Cresswell 1998; Rock and Goldberg 1999). Type 1 IFNs increase the expression of MHCI and MHCII molecules and activate the effector function of T cells, NK cells, and macrophages (Guidotti and Chisari 2001). Whether the mechanisms by which type 1 IFN regulate MHCI expression are similar to those mediated by IFN-γ is not clear.

The role of co-stimulatory and surface molecules

T-cell activation requires the signal derived from the recognition of specific MHC–peptide complexes by TCRs and also additional costimulatory signals provided by accessory molecules on T cells and specialized APCs. CD28 is a well-known costimulatory molecule expressed on naïve or primed T cells, which bind to B7-1 (CD80) or B7-2 (CD86) on APCs (Schwartz 1992; Azuma et al. 1993; Freeman et al. 1993; Lenschow et al. 1996; Alegre et al. 2001). After recognition of specific MHC–peptides and costimulatory molecules, T cells proliferate and produce IL-2. In the absence of costimulatory signals, the engagement of TCRs and MHC–peptide complexes could result in anergic T cells. Costimulatory signals also promote T-cell survival by inducing the expression of antiapoptotic Bcl-2 (Boise et al. 1993). The mechanisms by which costimulatory signals provided by CD28–B7 ligation facilitate T-cell proliferation and differentiation are still not clear. The signals from CD28–B7 ligation may increase the TCR signaling pathway or stimulate different pathways from TCR signaling (Vola and Lanzavecchia 1996). Costimulatory signals were found to reduce the number of TCRs required for stimulation of cytokine production and proliferation at the cellular level. There are other positive signals provided by activating receptors including NKG2D to facilitate CD8 T-cell responses and tumor immunity (Diefenbach et al. 2001). Besides positive costimulatory signals, inhibitory receptors including CTLA-4 were also found to inhibit T-cell activation by suppressing IL-2 and IL-2 receptor expression (Alegre et al. 2001).

The movement of T or B lymphocytes into lymphoid organs is mediated by adhesion molecules on lymphocytes interacting with receptors on the high endothelial venules (HEV). Many experiments prove that T or B cells prefer localization to specific tissues. Lymphocytes isolated from gut-associated lymphoid tissue tend to localize to Peyer's patches after being reinfused, whereas splenocytes prefer migrating to the spleen. Immune responses in nonlymphoid tissues induce the movement of lymphocytes into nonlymphoid tissues. Cytokines induce the expression of adhesion molecules on endothelium which mediate the migration of lymphocytes into the inflammation tissues (Issekutz 1992). Different cytokines induce expression of different adhesion molecules that control different stages of lymphocyte migration (Issekutz 1990). ICAM-1 (CD54) and ICAM-2 (CD102) expressed on endothelial cells are receptors for LFA-1 on leukocytes (Bevilacqua 1993). The expression of adhesion molecules can improve the interaction of T cells with endothelium and target cells. Several publications have indicated that the lack of expression of some adhesion molecules resulted in diminished immune responses.

THE MAJOR HISTOCOMPATIBILITY COMPLEXES AND TCRS

The binding affinity of peptides to MHC

MHCI molecules consist of a heavy chain and β^2-microglobulin. β^2-Microglobulin associates noncovalently with the extracellular region of the heavy chain to form the peptide-binding region. After peptide binding, stable peptide–MHCI complexes are presented on the cell

surface. In TAP-deficient RMA-S cells, MHCI complexes are not stable at 37°C without optimal peptide binding (Townsend et al. 1989; Cerundolo et al. 1990). MHCI molecules are detectable at 26°C with specific antibody in RMA-S cells, which are used to screen H-2 K^b-binding peptides. To measure the binding affinity of peptides to MHC, MHCI heavy chains are purified to associate with β^2-microglobulin and labeled peptides (Quesnel et al. 1996). The alternative approaches are to label heavy chain or β^2-microglobulin for the measurement of peptide-binding affinity. The binding affinity of peptides to MHC and the stability of MHC–peptide complexes have been shown to affect the number of MHC–peptide complexes expressed on the cell surface. The binding affinity to MHC also affects the immunogenicity of peptide epitopes for the induction of CD8 CTL responses (Sette et al. 1994; van der Burg et al. 1996). The actual amino acid residues that are important for the binding of peptide epitopes to MHC with appropriate affinity need further investigation. The minimal number of specific MHC–peptide complexes required for activation of CD8 CTL-mediated cytolysis has been suggested to be from one to a few hundred (Christinck et al. 1991; Kageyama et al. 1995; Sykulev et al. 1996). Several factors affect the antigenicity and immunogenicity of peptide epitopes, including the density and number of specific MHC–peptide complexes; however, the number and density of these complexes required for the induction of CD8 CTL responses and CD8 CTL-mediated lysis of target cells are not clear.

The binding affinity and avidity of MHC–peptide complexes to TCRs

Soluble MHC–peptide complexes can be produced with purified MHC heavy chain, β^2-microglobulin, and peptides, and the binding affinity between TCRs and MHC–peptide complexes has been measured with purified MHC–peptide complexes and TCRs. The binding affinity between TCRs and MHC–peptide complexes is lower than that between antibody and antigen (Matsui et al. 1991). The detection of the number of specific CD8 T cells is difficult using specific monomeric MHC–peptide complexes resulting from low binding affinity. Although the number and density of MHC–peptide complexes required for the activation of CD8 CTL-mediated lysis of target cells are not clear, T-cell recognition of specific MHC–peptide complexes could involve multiple binding of TCRs (Altman et al. 1996; Reich et al. 1997; Rubio-Godoy et al. 2001; Demotte et al. 2002; Dutoit et al. 2002; Knabel et al. 2002; Valmori et al. 2002; Wu et al. 2002). Multimeric MHC–peptide complexes have been developed to measure the frequency of specific CD8 T cells (Altman et al. 1996; Rubio-Godoy et al. 2001; Dutoit et al. 2002; Knabel et al. 2002; Valmori et al. 2002) (see Figure 2, p. 425). However, appropriate methodology to measure the avidity of T-cell recognition of specific MHC–peptide complexes on the surface of target cells by TCRs is still not available. In several studies, high-avidity CD8 CTL lines or clones that recognize the target cells pulsed with lower concentration of specific peptides have been suggested to provide better protection in vivo (Alexander-Miller et al. 1996; Herbert et al. 1999; Derby et al. 2001). Many hypotheses have also been proposed to explain the avidity of the recognition of MHC–peptide complexes by CD8 CTL, including the binding affinity of TCR to MHC–peptide complexes, maturation of the functional avidity of T-cell recognition and the number of TCRs required for recognition (Vola and Lanzavecchia 1996; Reich et al. 1997; Holler et al. 2001; Slifka and Whitton 2001). The mechanisms by which avidity plays a role in the recognition of MHC–peptide complexes by CD8 T cells and the mediation of cytolysis and cytokine production remain to be defined.

Unconventional T cells

ADRIAN HAYDAY AND CARRIE STEELE

Defining unconventional T cells 1
Subtypes of unconventional T cells: γδ T cells 2
Subtypes of unconventional T cells: αβ T cells 7
References 12

DEFINING UNCONVENTIONAL T CELLS

It is now evident that both B lymphocytes and T lymphocytes need to be subdivided into distinct classes. For B cells, these classes comprise B1 cells commonly enriched in the peritoneum, and circulating B2 cells. As the distinct features of B1 cells have only become apparent in the past 25 years, as their functions remain enigmatic, and as B2 cells fully satisfy conventional assays for B-lymphocyte activity, B2 cells are most commonly regarded as 'conventional B cells', with B1 cells being viewed as 'unconventional'. This view of B1 cells as peripheral to core B-cell function is encouraged by their apparently varied representation in different species, and their presence in humans is still uncertain. Likewise, it is now common to view T cells as comprising 'conventional', circulating αβ T cells, defined by expression of the heterodimeric αβ T-cell receptor (TCR), and 'unconventional T cells' which, like B1 cells, are of enigmatic function and highly varied in their representation in different species. Nevertheless, any view of immunology that discounts unconventional T cells from playing critical roles in host defense is ill-judged, ignoring their evolutionary conservation over at least 400 million years, and the emerging evidence that they have potent immunoprotective and immunoregulatory roles that are germane to infectious disease, tumor surveillance, and autoimmunity.

The contrast of unconventional T cells with conventional T cells inevitably requires clear operational criteria for conventional T-cell activity. These are: (1) recognition of peptide antigens presented by highly polymorphic major histocompatibility complex (MHC) proteins; (2) negative selection during development by high-affinity engagement of self-antigens; (3) antigen priming in the secondary lymphoid tissues (lymph nodes and spleen) by 'professional' antigen-presenting cells (APC); and (4) commitment of a subset of the primed T-cell repertoire to the long-term memory pool that composes cellular immunity. Collectively, unconventional T cells appear to fail most (perhaps all) of these four criteria. Thus, (1) they are not restricted by conventional, highly polymorphic MHC; (2) it is not certain that they are negatively selected by engagement of autoantigens during development, but rather may be positively selected; (3) their patterns of systemic circulation are commonly (perhaps invariably) distinct, with greater constitutive association with tissues rather than with lymph nodes, spleen, and bone marrow; and (4) the evidence that they contribute to long-term memory is equivocal, with the greater mass of data implying that their primary contribution is to the early phases of immune responses, preceding the activation of conventional T cells.

By these operational criteria, the activities of unconventional T cells would seem complementary to those of conventional T cells. Such complementarity could provide a powerful argument for the cells' evolutionary conservation. At the same time it is unwise to view unconventional and conventional T cells as operating entirely independently in their contributions to immune responses. Growing evidence indicates that unconventional T cells have a potent capacity to regulate conventional T-cell responses, and are thus important factors to consider in the understanding and treatment of immunopathologies such as inflammation, allergy, and antigen-specific autoimmunity.

SUBTYPES OF UNCONVENTIONAL T CELLS: γδ T CELLS

Perhaps the most galvanizing development in the recognition of T-cell heterogeneity was the discovery in 1984 of a TCR gene cDNA (complementary DNA), TCR γ, that encoded neither the TCR α chain nor the TCR β chain (Saito et al. 1984). Within 3 years, the existence of TCRγδ$^+$ cells was firmly established. Antigen recognition by TCRγδ is critically different from that of conventional αβ T cells. In particular, mice that are deficient in polymorphic MHC class I and/or II molecules show substantial defects in circulating αβ T cells, whereas the γδ cell compartment is largely unaffected (Correa et al. 1992; Bigby et al. 1993). The fact that before 1984 no one had predicted the existence of γδ cells strongly suggested that conventional assays for T-cell activity – primarily the development of antigen-specific immunity – were fully satisfied by αβ T cells. In turn, this suggested from the outset that γδ cells use their unconventional TCR specificities to contribute to immune responses in unconventional ways: much work over the past 15 years has supported this idea. To consider γδ cells more clearly, one must recognize that the γδ cell compartment itself is made up of several distinct subcompartments.

TCRγδ$^+$ dendritic epidermal T cells

Murine dendritic epidermal T cells (DETC) are arguably the prototypical nonconventional T cell, and their study introduces many features of nonconventional T cells more broadly. DETCs are an example of intraepithelial lymphocytes (IEL): rather than circulating, they are constitutively associated with a single tissue, which, in the case of DETCs, is the epidermis. Unlike conventional T cells, which are round cells dominated by their nucleus, DETCs appear in situ as dendritic cells that collectively form an anastomosing network in contact with the majority of basal keratinocytes. Several experiments over the past decade have demonstrated that DETCs can directly engage heat-shocked or malignantly transformed keratinocytes, provoking cytokine release and/or target cell killing (Havran et al. 1991). Thus, DETCs as well as other IELs have been considered to contribute to a 'first line of defense' (Janeway et al. 1988). There is, by contrast, little evidence that DETCs interact with professional APCs, such as Langerhans' cells which prime the conventional T-cell response.

DETC progenitors are the first to colonize the murine fetal thymus (Havran and Allison 1988) and, consistent with their failure to engage conventional class I or class II MHC, they complete development without the acquisition of CD4 and CD8 expression which is a signatory feature of conventional αβ T-cell development. Seemingly, they leave the thymus after positive selection, but until their TCR ligand is characterized the details of this event will remain opaque. The basis for homing to and residence within the skin has also not been elucidated, but it is likely that different molecules contribute to the two processes. Once the perinatal wave of skin colonization by DETCs has occurred, the thymus loses its capacity to regenerate DETCs (Ikuta et al. 1990). Possibly, stem cells from which DETCs can be replenished exist in some compartment of the skin (e.g. the dermis), but if this is the case, those progenitors, like DETC themselves, are vulnerable to surface ultraviolet irradiation, because such treatment causes long-term DETC ablation (Aberer et al. 1986).

Similar to other thymocytes, developing DETC progenitors utilize recombinase-activating gene (RAG)-mediated somatic DNA recombination to generate a TCR. By the quasi-random and imprecise joining of any one of a large number of variable (V) gene segments with any one of a large number of diversity (D) gene segments, which is in turn joined to any one of a large number of junctional (J) gene segments, RAG-mediated recombination can generate immensely diverse receptor repertoires characteristic of the T- and B-cell compartments (Tonegawa 1983). In curious contrast, DETCs express a monomorphic Vγ5/Vδ1 TCR (Asarnow et al. 1988).

Although its ligand is currently not elucidated, the simplicity of the DETC TCR is consistent with the hypothesis that DETCs recognize a generic self-antigen, induced on infected or transformed epithelial cells by a wide range of cellular insult (Janeway et al. 1988). The basis for this hypothesis is that IELs resident within epithelia will not have the opportunity to sample millions of different antigens presented by APCs in the lymph nodes of infected mice, but must therefore rely on activation by a self-antigen that is expressed selectively on infected or transformed epithelial cells.

The TCR is not the only lymphocyte surface molecule that may be engaged in this fashion. Activated DETCs, along with other cytolytic T cells and natural killer (NK) cells, express an activating receptor, NKG2D, that engages any one of a number of nonconventional MHC class IB gene products, e.g. Rae-1 (mouse and human), H60 (mouse), ULBP (human), and MICA/MICB (human) (Bauer et al. 1999; Cerwenka et al. 2000; Diefenbach et al. 2000; Cosman et al. 2001). These molecules resemble conventional MHC class I proteins in general structural features, but most probably do not present antigenic peptides (Li et al. 1999, 2002). As peptide binding stabilizes conventional class I and II MHC proteins, the stable display of peptide–MHC complexes by an APC signifies its 'immunological visibility' to conventional T cells. By contrast, the immunological visibility of cells expressing peptide-independent MHC-related molecules to NKG2D$^+$ lymphocytes is regulated at least in part by strictly inducible gene expression.

Thus, Rae-1 is expressed primarily in the embryo (Zou et al. 1996), and at negligible levels in normal adult tissue (Cerwenka et al. 2000; Diefenbach et al. 2000), but its expression increases in vivo in skin epithelial cells exposed to transforming chemicals (Girardi et al. 2001). Likewise, the expression of MICA/B is upregulated on heat-shocked or transformed epithelial cells of the human gut (Groh et al. 1996, 1999) where there is an additional population of resident TCRγδ$^+$ cells (see below). Currently, the cell signaling pathways that tightly regulate the expression of 'stress-inducible' class IB MHC are unknown.

DETCs can also express receptors, notably Ly49E (Van Beneden et al. 2002), that are associated with NK cells, and not commonly expressed by conventional T cells. The engagement of such receptors limits T-cell activation, implying that the immunological visibility of skin epithelial cells also relies on overcoming the engagement of inhibitory receptors, either by reducing or altering the expression of their ligands, or by quantitatively overwhelming the cell via activating receptor engagement.

There has to date been little effective testing of the roles of DETCs in the protection of mouse skin against infection. Nevertheless, the physiological relevance of DETC engagement of transformed keratinocytes was strongly implied by the finding that TCRγδ-deficient mice are substantially more susceptible to multiple, diverse protocols for the induction of squamous cell carcinoma (Girardi et al. 2001). Indeed, the mice are more reproducibly susceptible than are TCR αβ–deficient mice. These studies potentially provide a model for the protective activities of TCRγδ$^+$ IELs against the development of solid tumors in humans (see below).

Once activated, DETCs, as with many other nonconventional T cells, display a clear potential for cytolytic and T-helper (Th)1-type effector responses that can account for their local protective activities. In addition, DETCs and other IELs express well-characterized chemokines, such as RANTES and lymphotactin (Boismenu et al. 1996), as well as enigmatic molecules such as thymosin β4 (Shires et al. 2001), which have potent anti-inflammatory activities in certain assays. Perhaps consistent with this, DETCs and other IELs have immunoregulatory activity and, on certain genetic backgrounds, DETC deficiency leads to striking pathological inflammatory infiltrates of the skin which are provoked by αβ T-cell responses to environmental antigens (Girardi et al. 2002). Indeed, on particular genetic backgrounds, the pathognomonic outward appearance of TCRγδ$^{-/-}$ mice is visible to the naked eye. Although the TCR is apparently involved in immunoregulation by DETCs, the relevant ligand is again unelucidated. Indeed, immunoregulation might occur following direct interaction of DETCs with activated infiltrating lymphoid cells, or as an indirect by-product of TCR-mediated DETC engagement of activated epithelial cells.

Importantly, the phenotypic analysis of TCRγδ$^{-/-}$ mice informs us that DETCs provide a multifaceted protection of epithelial integrity, ranging from the eradication of dysregulated epithelial cells to the inhibition of tissue disruption by systemic lymphoid cells. A further contribution of DETC activity to the maintenance of epithelial integrity is evident in the reported expression by DETCs of fibroblast growth factors that promote keratinocyte growth (Boismenu and Havran 1994; Jameson et al. 2002). Although this may appear paradoxical given the capacity of DETCs to kill epithelial cells, the data are collectively interpreted to suggest that, after target cell eradication, DETCs subsequently contribute to wound healing.

Clearly, the initial view of DETCs as cells that use a monomorphic TCR to target dysregulated epithelial cells as part of a pseudo-innate immune response is insufficient to accommodate the complexity of DETC functions. Conceivably, despite their expression of a single TCR, DETCs may comprise functionally distinct subsets, capable of cytolysis, immunoregulation, and epithelial cell growth promotion, respectively. This hypothesis is being tested at present.

Although DETCs capably illustrate the impressive functional potential of 'local', tissue-associated T cells, the general relevance of the lessons learned has been questioned, given that DETCs are not obviously conserved in humans. Indeed, some have wondered whether 'DETC functions' are an idiosyncrasy of relatively short-lived mammals, such as rodents, which have large litter sizes, placing less emphasis on the long-term survival of the individual (sometimes cited as the key provision of antigen-specific memory in the conventional adaptive immune system). This is clearly not the case, because DETCs are conserved in cattle, large mammals with long lifespans that are more similar to humans than to mice. Therefore, the probability exists that 'local immune functions' exist in human skin, but are provided by other cell types. Thus, it has been reported that a unique TCR γδ$^+$ subset resides in the dermis of healthy human skin (Holtmeier et al. 2001), and there are increases in cutaneous γδ cells in scleroderma, an inflammatory pathology characterized in part by fibrotic wound healing, and possibly promoted by human γδ cells. Given the potential of DETCs to be activated via the NKG2D receptor, it is also possible that local immune function in human skin is provided by NK cells or myeloid cells that can likewise use the NKG2D pathway to respond to epithelial cell dysregulation and/or activated inflammatory infiltrates. In sum, the study of DETCs emphasizes the need for better understanding of local immune function in cutaneous immune responses in humans.

A second important contribution of DETCs to the study of human immunology is the potential to improve our understanding of other epithelia that also harbor TCRγδ$^+$ IELs, both in mice and in humans.

TCRγδ$^+$ IELs in other tissues in mice and humans

In mice, the functional and molecular relatedness of IELs that characterize different epithelia – the skin, reproductive tissue, tongue, intestine, and (reportedly) lung – has yet to be firmly established. Unlike the case of DETCs, direct equivalents of such cells are evident in certain human tissues, e.g. the human small intestine. Given the very large surface area of the human gut (>200 m^2), it is likely that IELs will account numerically for a major fraction of human T cells.

Similar to DETCs, the TCRs of IELs in different tissues show limited diversity. Murine vaginal and tongue-associated IELs express a single predominant Vγ chain (Vγ6) (Lafaille et al. 1989) distinct from that in skin (Vγ5) (Asarnow et al. 1988) and the gut (Vγ7) (Bonneville et al. 1988; Goodman and Lefrancois 1988; Kyes et al. 1989; Takagaki et al. 1989). In the human gut, IELs express Vγ1 (Deusch et al. 1991), by contrast to Vγ2 expressed by most systemic γδ cells. The intestinal IELs of mice and humans show some junctional diversity and some variation in Vδ usage, but the biological significance of this vis-à-vis antigen recognition is unresolved.

In the mouse, the IELs that populate the different tissues develop in sequential 'waves' in the fetal and neonatal thymus, with those in the skin preceding those in the reproductive tissue, which precede those in the gut (Havran and Allison 1988). Thus, it has been proposed that the association of particular TCRs (especially Vγ genes) with particular tissues reflects the sequential activation of gene segment usage. Whether or not this is true, the same association has quite naturally provoked the concept that each TCR recognizes a tissue-specific 'stress antigen' that would serve as a generic beacon of epithelial distress. The likelihood that each class of γδ TCR recognizes a clearly distinct entity is high because, by contrast to the usual situation in conventional T cells and B cells, individual Vγ genes share little homology and are very distinct from each other in the complementarity determining regions (CDR) CDR1 and CDR2 which would be predicted to form part of the antigen-binding surfaces (Arden et al. 1995b).

As was the case with DETC, there is scant evidence for a critical immunoprotective role of TCRγδ$^+$ IELs against pathogens that either enter or reside within epithelia. Indeed, whereas αβ T-cell-deficient mice showed high susceptibility toward a natural parasitic infection of the intestinal epithelium, the immunoprotective role of γδ cells was only exposed in mice that also lacked αβ T cells (Smith and Hayday 2000). Such data have encouraged some scientists to regard TCRγδ$^+$ cells as inferior to αβ T cells in their value to the host. However, when infected with a natural parasite of the intestinal epithelium, γδ-cell-deficient mice are not without phenotype: rather, they primarily show a defect in immunoregulation, manifest in aggressive αβ T-cell-dependent immunopathology (Roberts et al. 1996).

Also paralleling the findings with DETCs, human Vγ1/Vδ1$^+$ IELs isolated from surgical specimens of bowel cancer would kill the cancer cells after engagement of the NKG2D ligand, MICA (Groh et al. 1998). Vγ2/Vδ2$^+$ cells would not do this, provoking the concept that MICA engages TCRγδ as well as NKG2D (Groh et al. 1998; Wu et al. 2002). A precedent for such ligand promiscuity might be found in the binding of conventional MHC class I simultaneously to TCRαβ and to CD8, or in the binding of human HLA-C or murine Qa-1 to TCRαβ and to NK receptors (see below). Indeed, cytolysis by Vδ1$^+$ IELs could be inhibited with anti-MICA and anti-TCRγδ monoclonal antibodies. To clarify the capacity of the Vγ1/Vδ1 TCRs to bind MICA, a T-cell line that does not express NKG2D was transfected with TCR chains from MICA-responsive γδ clones or MICA-unresponsive clones (Wu et al. 2002). Cells expressing TCRs derived from responsive clones bound MICA tetramers, whereas those transfected with TCRs derived from unresponsive clones did not. Clearly, if these data are correctly interpreted, it should be possible to demonstrate direct binding of MICA to a soluble Vγ1/Vδ1 TCR by surface plasmon resonance.

The same experimental approach might usefully support the evidence that human T-cell clones expressing collectively Vγ1 paired with Vδ1.4 or Vδ2 bind to CD1c (Spada et al. 2000). CD1 proteins constitute a further subset of nonpolymorphic class IB MHC molecules. There are two groups of CD1 proteins: group 1 includes CD1a, Cd1b, and Cd1c, which collectively are found in humans but not in mice; group 2 includes CD1d which is conserved (Gumperz and Brenner 2001). All CD1 proteins have deep hydrophobic grooves that permit them to present lipid molecules to reactive TCRs (see below).

In sum, TCRγδ$^+$ IELs in the gut display both protective and immunoregulatory functions. The molecular potential for such actions was readily revealed by the comprehensive cataloguing of genes expressed by murine gut TCRγδ$^+$ IELs. These analyses undertaken by microchip array and by serial analysis of gene expression (SAGE) have shown that more than 2 percent of IEL mRNA is devoted to the expression of the cytolytic effector molecules, granzymes A and B, and the immunoregulatory chemokine, RANTES (Shires et al. 2001).

Systemic γδ cells

γδ cells can be found in the peripheral blood, spleen, and lymph nodes, but again their representation varies greatly from very rare (humans and mice) to more than 50 percent of systemic CD3$^+$ cells (calves). Nevertheless,

the low numbers of systemic γδ cells in humans can increase substantially, particularly during bacterial infections, to more than 40 percent of $CD3^+$ (PBL). Systemic γδ cells, similar to $TCR\gamma\delta^+$ IELs, use limited Vγ and Vδ pairings, but, as these pairings are dissimilar from those used by $TCR\gamma\delta^+$ IELs, systemic γδ cells and $TCR\gamma\delta^+$ IELs may recognize distinct classes of antigen. Moreover, in contrast to $TCR\gamma\delta^+$ IELs, systemic γδ cells often display substantial junctional diversity in their TCRs. Indeed, the junctional diversity of TCRγδ may be more diverse than either TCRαβ or Ig.

Additional evidence that systemic γδ cells may not be limited to the recognition of MHC-like structures is provided by an indepth analysis of TCR structure. The CDR1 and CDR2 regions of γ and δ chains are longer than those of TCRα and -β (Arden et al. 1995a; Clark et al. 1995), and although the CDR3 regions of TCRα and -β chains are limited to 6–12 nucleotides (interpreted as the constraint imposed by binding to the relatively 'flat' peptide/MHC surface), the CDR3 of TCRδ, similar to that of IgH, is extremely varied, (6–22 nucleotides), suggesting no constraining topology of γδ ligands (Rock et al. 1994). Nevertheless, how such diversity translates into antigen specificity is not yet clear.

The crystal structure of an isolated human Vδ3 chain showed that CDR1 and CDR3 assumed a conformation similar to TCRαβ, whereas CDR2 assumed a conformation more like IgH (Li et al. 1998). More recently, a structure of a complete human Vγ2Vδ2 TCR confirmed that CDR2 of Vδ2 more closely resembled IgH than TCRαβ, although the significance of this with respect to antigen binding is also unclear (Allison et al. 2001).

Consistent with their failure to recognize antigen restricted by polymorphic MHC class I or II, systemic γδ cells in mice and humans usually express neither CD4 nor CD8, and derive directly from $CD4^-CD8^-$ ('double-negative') thymocytes. In humans, the bulk of systemic γδ cells arise from fetal thymic progenitors.

In the mouse, about 0.5 percent of systemic γδ cells bind to the nonconventional, peptide-independent β_2-microglobulin-associated MHC class 1B molecule, T10/T22 (Crowley et al. 2000). To date, this is the only γδ TCR reactivity for which a direct biochemical interaction has been shown. Using a murine γδ T-cell hybridoma, a reactivity to MHC class II has also been reported, although recognition does not focus on the peptide-containing α1α2 helical groove that is seen by TCRαβ (Chien et al. 1996). Systemic murine γδ cells have also been proposed to recognize the nonclassic class I molecule, Qa-1 (Vidovic et al. 1989), although this was in the context of presenting a nominal, nonphysiological antigen comprising a mixture of polymers of glutamic acid, aspartic acid, and tyrosine.

In humans but not mice, a highly unconventional TCR specificity has been reported in the capacity of peripheral blood, $V\gamma2V\delta2^+$ cells to be stimulated by low-molecular-mass, nonpeptidic chemicals such as isopentenyl pyrophosphate (Tanaka et al. 1995) and, at much higher concentrations, alkylamines (Bukowski et al. 1999) (Figure 1). These chemicals can be isolated from extracts of bacteria, parasites, and algae, but at least some are absent from vertebrates. Although direct chemical binding to the TCR has not been shown, the possibility exists that these chemicals are relatives of 'true' high-affinity antigens which, when clearly identified, will permit direct binding to be shown. In this vein, human $V\gamma2V\delta2^+$ cells are strikingly responsive to a mutant strain of *Escherichia coli* defective in the *lytB* gene, an essential enzyme in the 2-C-methylerythritol-4-phosphate (MEP) pathway of isoprenoid biosynthesis (Altincicek et al. 2001). The hyperresponsiveness presumably reflects reactivity toward an accumulated, biologically active intermediate that has been identified as a pyrophosphated molecule of 262 Da (Eberl et al. 2002).

Such specificities may enable systemic $V\gamma2V\delta2^+$ cells to recognize microbial products directly, but, if this is the case, it remains uncertain how the low-molecular-mass, hapten-like antigens can activate the T cell, conventionally achieved via TCR crosslinking of at least a TCR dimer. Likewise, how would an activated T cell focus in on a target, now thought to require synapse formation with an engaged cell? Possibly the low-molecular-mass antigens are presented by a novel antigen presentation system. Consistent with this hypothesis, the recognition by human γδ cells of another class of low-molecular-mass chemicals, the aminobisphosphonates, requires a myeloid-presenting cell (Miyagawa et al. 2001).

As well as being produced by microbes, some low-molecular-mass chemicals that stimulate systemic γδ cells may be products of increased metabolism, e.g. intermediates in protein farnesylation in actively growing cells. Moreover, alkylamines can be generated by catabolism of the amino acid theamine, which exists in tea. The biological relevance of these aspects is not elucidated, although it has been proposed that peripheral blood γδ cells might be primed by dietary components to respond rapidly to microbes and/or transformed cells. Reactivity of peripheral blood γδ cells to tumors was reported over a decade ago in the recognition of Daudi B-cell lymphomas by $V\gamma2V\delta2^+$ cells (Fisch et al. 1990). However, in this case the recognition was proposed to be of surface-bound heat shock proteins (HSP).

Murine γδ cells derived from the thymus have also been reported to recognize HSPs (O'Brien et al. 1989), although there is again no biochemical evidence for this as yet. Moreover, it has become increasingly clear that surface-bound HSPs can be engaged by a variety of non-TCR receptors on lymphoid and/or myeloid cells (Srivastava 2002). Thus, the mechanism and significance of HSP recognition by γδ cells remains uncertain. As systemic γδ cells are much more abundant in bovine

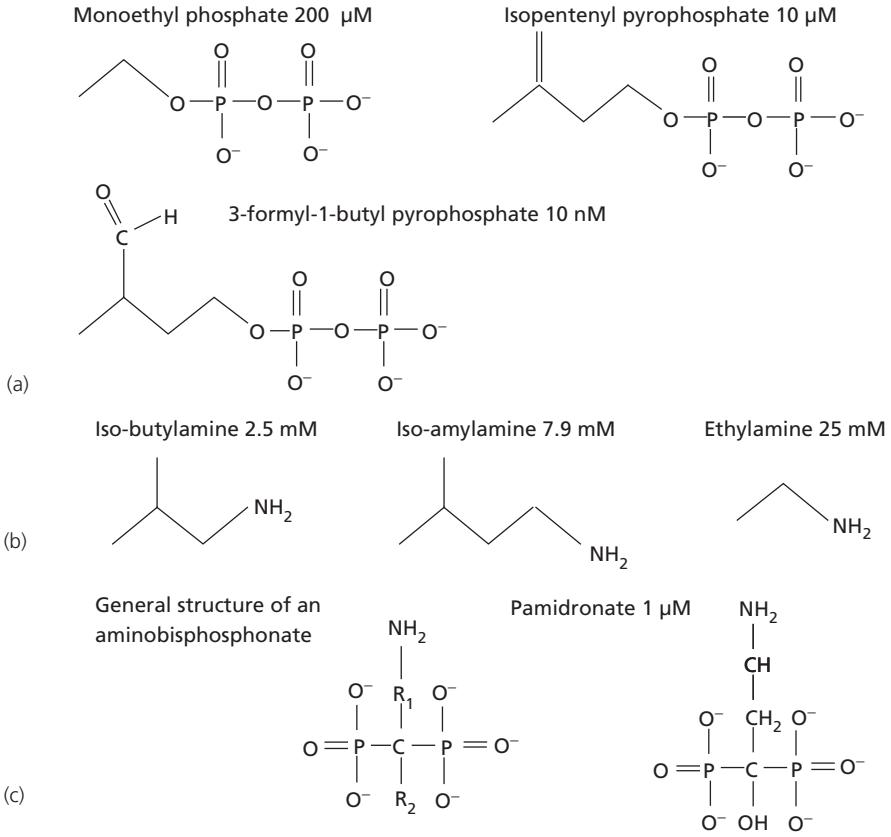

Figure 1 *Low-molecular-mass antigens for γδ cells. Structures of* **(a)** *phosphate antigens,* **(b)** *alkylamines, and* **(c)** *aminobisphosphonates. Active concentrations are indicated.*

species, particularly during the first year of life, it would be interesting to determine those cells' reactivities. Although such studies are ongoing, emerging data suggest that those cells too are unconventional, not restricted to conventional MHC.

The biological functions of systemic γδ cells have again been assigned as cytolytic and/or immunoregulatory. In certain strains of mice infected with Coxsackie virus B3, a Th1-mediated myocardial inflammation develops that is dependent on γδ cells. Rather than being directly causative of the inflammation, the role of γδ cells is to eradicate, by fas-mediated cytolysis, virus-responsive Th2 cells (Huber et al. 1999). A broader involvement of unconventional cytolytic T cells in immune regulation is apparent from the identification of regulatory $CD8^+$ αβ T cells, described in a later section.

The activation of human $TCR\gamma\delta^+$ PBLs by low-molecular-mass microbial antigens has been linked to the dramatic expansions that the cells may show in cases of bacterial infection. Human γδ cells reactive to low-molecular-mass mycobacterial antigens express cytolytic chemicals such as granulysin, and may target mycobacteria-infected macrophages. Although a critical contribution of systemic γδ cells to protection against mycobacteria has not been clearly validated, and although no mouse γδ cells have been identified that respond to low-molecular-mass chemicals, γδ-deficient mice inoculated with mycobacteria via aerosols showed altered, disseminated granulomas, consistent with the cells' role in regulating activities of other cells of the immune system (D'Souza et al. 1997). Thus, there are good grounds for viewing γδ cells as an important component of the host response to mycobacteria in mice and humans.

In the rare instances that critical contributions of γδ cells to host protection have been documented in the mouse, they primarily expose a role for γδ cells early in infection, before the priming and expansion of conventional MHC-restricted T cells in the lymph nodes. Thus, it can be considered that such nonconventional T cells collaborate with NK cells in limiting the spread of infection, before the development of antigen-specific immunity. In support of this, there has as yet been no identification of a cloned murine γδ cell line that will transfer antigen-specific immunity upon adoptive transfer to a naïve recipient. Recently, the presence of immunoprotective, mycobacteria-reactive $TCR\gamma\delta^+$ memory cells was reported in primates (Shen et al. 2002), but until we have an improved molecular definition of memory cells (that will probably emerge from contemporary genomic and proteomic studies), the

contribution of γδ cells to a memory pool remains uncertain.

Moreover, one possibility relating to γδ cells and other nonconventional T cells is that they are positively selected on autoantigens in the thymus, rather than the negative selection imposed on conventional T cells that are autoreactive. Were this to be the case, the cells could emerge from the thymus in a primed state, capable of very rapid responses to antigen in the periphery. Such a situation has recently been described for unconventional *Listeria*-reactive αβ T cells (see below). Clearly, rapid responses cannot depend on extensive clonal expression of an effector cell (because there would not be time to achieve this). Consistent with this, γδ cell responses to putative antigens, such as low-molecular-mass chemicals or HSPs, seem to occur at the population rather than at the clonal level. Such behavior is consistent with the hypothesis (discussed above) that the fundamental contribution to antigen recognition may be conferred by the CDR1 and CDR2 regions of the Vγ and Vδ gene segments used by the responding populations.

SUBTYPES OF UNCONVENTIONAL T CELLS: αβ T CELLS

TCRαβ$^+$ IELs

The murine intestinal IEL compartment is composed numerically of three main subsets: TCRγδ$^+$ IELs, and two subsets of αβT cells expressing the CD8αα homodimer and the CD8αβ heterodimer, respectively. The CD8αβ heterodimer is the form of CD8 expressed by conventional, systemic, MHC class-I-restricted αβ T cells. Consistent with this, TCRαβ$^+$ CD8αβ$^+$ IELs share many properties with conventional T cells. By contrast, CD8αα expression on systemic T cells is rare and, by several criteria, TCRαβ$^+$CD8αα$^+$ IELs are non-conventional T cells, with much in common with TCRγδ$^+$ IELs. Again, their representation in different species varies, with these IELs being rarer than TCRγδ$^+$ IELs in the adult human gut.

TCRαβ$^+$CD8αα IELs are not restricted by conventional class I or II MHC. Although there are as yet no biochemical data on TCRαβ$^+$CD8αα specificity, the cells, like TCRγδ$^+$ IELs, may recognize nonclassic MHC proteins, transcriptionally upregulated as part of a response to 'stress'. Indeed, their development is strongly regulated by Qa-2 (Das et al. 2000), an MHC class 1B molecule, which similar to MICA and Rae-1 does not require peptide loading by transport associated with antigen processing (TAP) but, unlike MICA and Rae-1, is paired with β_2-microglobulin.

To date, no examples of pathogen-specific, TCRαβ$^+$CD8αα$^+$ IELs have been described. Like TCRγδ$^+$ IELs, some TCRαβ$^+$CD8αα$^+$ IELs may mature in situ, in extrathymic cryptopatches that were recently identified in the murine small intestine (Kanamori et al. 1996). However, under normal circumstances, most probably develop in the thymus. The cells' gene expression profile, sampled as a population, is almost identical to that of TCRγδ$^+$ IELs, with strong potential for cytolysis, and the production of Th1 cytokines and chemokines. In addition, both sets of nonconventional T cells express poorly characterized molecules (e.g. interleukin (IL) 16 and Toll-like receptor (TLR) 8) that may contribute substantially to the delivery and regulation of their effector function (Shires et al. 2001). Not surprisingly, analyses of animal physiology have shown that TCRαβ$^+$CD8αα$^+$ IELs (similar to TCRγδ$^+$ IELs of the gut and of the skin) downregulate tissue inflammation provoked by conventional αβ T cells (Poussier et al. 2002). Both nonconventional TCR αβ$^+$ IELs, and TCR γδ$^+$ IELs may be regulated in part by inhibitory NK cell receptors, such as Ly49E which are expressed on a subset of each cell type.

Unconventional systemic αβ T cells: CD1d-reactive cells

The prototypic αβ T cell exhibiting limited TCR diversity is the NKT cell that expresses the NK1.1 marker (CD161) and that in mice and humans recognizes the conserved group 2 CD1 antigen, CD1d. Most NKT cells express an invariant TCRα chain (Vα14/Jα281 in mouse; Vα21/JαQ in humans), paired with a limited repertoire of TCRβ chains (MacDonald 2002). The development of multivalent CD1d reagents has identified CD1d reactivity in a broader set of cells than those expressing only the signatory TCR and NK1.1. Moreover, not all NK1.1$^+$ cells react to CD1d. Thus, the value of the term 'NKT' is operationally useful, but should not be overinterpreted.

Following the identification of murine NKT cells, autoreactive against CD1d (Bendelac et al. 1995), it was observed that the cells' responses were enhanced by the glycosylated sphingolipid α-galactosylceramide (α-GalCer), a model antigen derived from a marine sponge (Kawano et al. 1997) (Figure 2). Other α-linked glycolipids activate NKT cells, whereas β-linked glycolipids, which more closely resemble mammalian lipids, do not. α-linked glycolipids are not normally found in mammalian cells, but may be found in particular fetal tissue, in the kidney or intestine, or in transformed cells (Gumperz and Brenner 2001). Physiological antigens presented by CD1d are only now being identified (Zhou et al. 2004), although at least some are thought likely to be self-encoded because NKT cells are present at essentially normal levels in germ-free mice. The prospect that more than one self-antigen may be recognized is suggested by the fact that a panel of NKT clones showed quite different responses to cells transfected with CD1d,

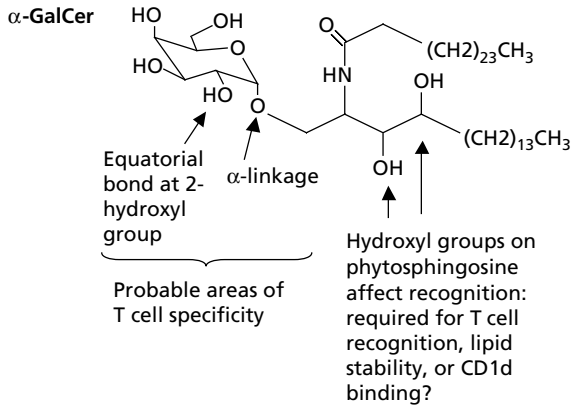

Figure 2 *Murine NKT cells are reactive to α-galactosylceramide (α-GalCer) presented by CD1d. NKT cells show fine specificity for the α anomer of galactose, and for an equatorial hydroxyl group at carbon 2. Removal of the hydroxyl groups at positions 2 and 3 of the phytosphingosine also prevented recognition, but this could be the result of decreased lipid stability or CD1d presentation.*

probably reflecting a spectrum of reactivities to different CD1d–lipid complexes displayed by the different transfectants.

CD1d-reactive cells have been assigned a plethora of functions, with a capacity to secrete large amounts of cytokines, including IL-4, IL-10, and interferon γ (IFN-γ) implicating the cell in immunoregulation (Gumperz and Brenner 2001). The NKT cytokine spectrum also implies that some nonconventional T cells are not constrained by the Th1/Th2 paradigm. Altered development of autoimmune disease has been reported in NKT-deficient animals such as $CD1d^{-/-}$ mice, on the appropriate genetic backgrounds. After infection with *Borrelia burgdorferi* (the etiological agent of Lyme disease), $CD1d^{-/-}$ mice displayed an altered (rather than a diminished) immune response (Kumar et al. 2000). Collectively, these data have strongly suggested that NKT cells respond rapidly to perturbation (e.g. infected or transformed cells), by coordinating the actions of other cells of the immune system. Thus, as with γδ cells, these unconventional T cells may make use of limited TCR diversity to recognize generic beacons of host dysregulation and activate immune responses, in a manner not dissimilar from the actions of dendritic cells or macrophages. Interestingly, large numbers of NKT cells are found in the liver, which is the organ responsible for releasing acute phase response mediators.

This notwithstanding, the biology of NKT cells may differ from that commonly attributed to γδ cells in that NKT cells emerge relatively late in thymic ontogeny, compared with the fetal and perinatal emergence of $TCR\gamma\delta^+$ IELs. Given this, the raison d'être of NKT cells may be to regulate conventional αβ T cells, rather than to contribute intrinsic immunoprotective capacities, as has been proposed for $TCR\gamma\delta^+$ cells. Perhaps consistent with this, the positive selection of NKT cells in the thymus is critically influenced by $CD4^+CD8^+$ 'double-positive' thymocytes, which are signatory progenitors of conventional αβ T cells (Bendelac 1995).

CD1a, -b, -c reactive αβ T cells

Numerous T cells have been identified that are specific for various glycolipid antigens presented by CD1a, CD1b, or CD1c. The cells express diverse TCRs, and have high specificity for the surface-exposed carbohydrate heads of glycolipid antigens that are anchored by their acyl chains deep within the hydrophobic core of the antigen-presenting pocket (Figure 3). CD1b will present mycobacterial cell wall-derived glycolipids, but CD1 molecules may also present endogenous ligands. In sum, the biological distinction between self and nonself that is a core parameter of conventional αβ T-cell activity remains enigmatic for the bulk of CD1-reactive T cells, as it does for γδ cells.

Like γδ cells, unconventional CD1-reactive T cells are primarily Th1/cytolytic $CD4^-CD8^-$ (double-negative (DN)) cells, but are not exclusively so. Hence, their true representation, based exclusively on the analysis of the DN T-cell population, may have been underestimated, particularly in infections. As CD1a, -b, and -c genes are absent from the mouse genome, a role for CD1-reactive cells in infection has been inferred from human studies showing that cells reactive to CD1-presented mycobacterial isoprenoid lipid antigens are readily detectable in people with recent *Mycobacteria tuberculosis* infections. Of note, efficacious immune responses to mycobacteria have been associated with group 1 CD1 antigen expression by dendritic cells (DC).

Unlike expression of MHC class II recognized by conventional T cells, CD1 is highly expressed on immature DCs, before their activation and migration from the periphery to the lymph nodes. The potential therefore exists to activate CD1-reactive T cells directly in peripheral tissues, further supporting the view that unconventional T cells complement conventional T-cell activities by contributing locally to an early phase of the immune response. Interestingly, the different forms of CD1 appear to associate with lipid antigens in different intracellular compartments (Jayawardena-Wolf and Bendelac 2001; Winau et al. 2004), suggesting that a spectrum of antigen-processing events may stimulate different subsets of CD1-reactive cells to respond to either endogenously synthesized antigen (in transformed or infected cells) or exogenously acquired antigen (after phagocytosis).

In sum, CD1-reactive cells compose a potent and versatile response repertoire, and it therefore seems all the more surprising that this system is not conserved in mice. Arguably, the relatively higher abundance of $\gamma\delta^+$ cells in mice may partially substitute for the function of

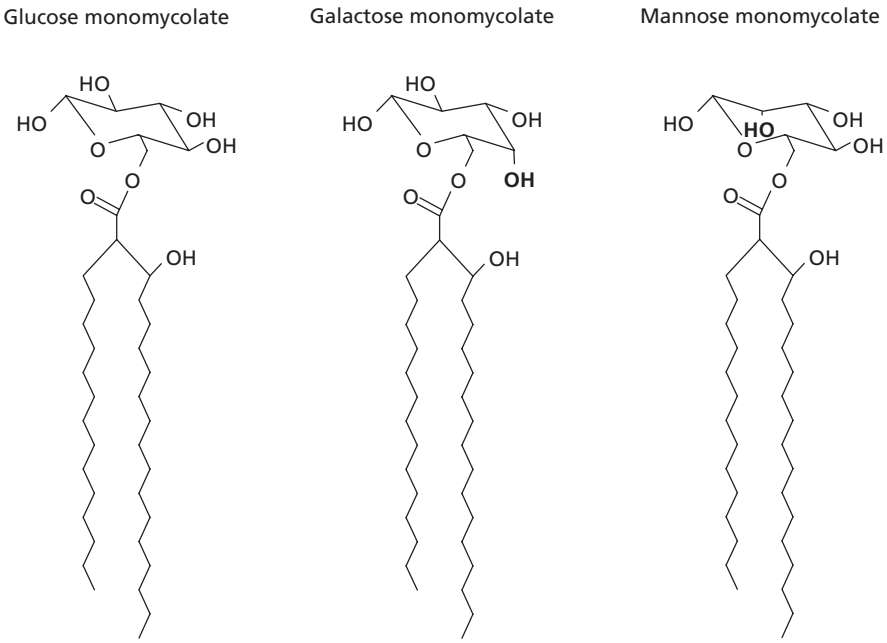

Figure 3 *αβ T cells exhibit fine specificity for glycolipid antigens presented by CD1b. Some αβ T cells recognize derivatives of mycolic acid, but not mycolic acid derivatized with galactose or mannose, which are stereoisomers of glucose and differ from glucose in the orientation of a single hydroxyl group.*

CD1-reactive cells, and CD1 reactivity of $\gamma\delta^+$ cells has been reported, ironically in humans (see above). Nevertheless, the reason that the specific constitutions of unconventional T-cell repertoires seem so variable across species remains poorly understood.

MR1-reactive αβ T cells

Another population of unconventional αβ T cells has been described in the lamina propria of the intestine in mice, humans, and cattle. These T cells express an invariant Vα7Jα33 TCR in humans (the homologous Vα19Jα33 in mice and cattle) (Tilloy et al. 1999). It was noted that this population was present in MHC class I and CD1 double-deficient mice, MHC class II-deficient mice, and TAP-deficient mice, but was missing in $\beta_2m^{-/-}$ mice. Therefore, candidate nonclassic MHC class I molecules were tested as potential ligands. As a result, this invariant T-cell population was found to be dependent on the presence of the nonclassic MHC class I molecule MR1 (Treiner et al. 2003). MR1 mRNA was previously reported to be expressed ubiquitously (Yamaguchi et al. 1997), although no antibody was available to confirm the distribution of the MR1 protein. It has since been found that, despite widespread mRNA expression, the MR1 protein is expressed only on the surface of activated B cells in the lamina propria. These B cells expressing MR1 activate the invariant Vα7Vα19 T cells to secrete transforming growth factor-β (TGF-β), which causes the B cells to class switch to IgA, the appropriate isotype for mucosal surfaces (Lantz, unpublished) (Figure 4). These recent findings concerning MR1-reactive αβ T cells parallel the findings from γδ cell biology in emphasizing the association of unconventional T cells with tissues and tissue-specific processes.

Qa-1 reactive/HLA-E reactive CD8αβ$^+$ αβ T cells

Other αβ T-cell populations are restricted by MHC class IB molecules of the H-2Q region, the counterpart of which in the human is the HLA-E molecule. After infection of mice with *Salmonella typhimurium*, large numbers of H-2Qa-1 reactive cells were described, whereas HLA-E-reactive T cells have been described in humans infected with *Mycobacterium tuberculosis*. Commonly, such unconventional MHC class Ib-reactive CD8αβ$^+$ αβ T cells appear to be constitutively activated, before infection, and may thus be primed to contribute to primary protection at early times after infection (see next section). However, an additional role has been proposed for MHC class Ib-reactive CD8αβ$^+$ αβ T cells, following the identification in the mouse of cells that respond to a Vβ8-derived peptide presented by Qa-1 on seemingly conventional Vβ8$^+$ CD4$^+$ TCRαβ$^+$ T-helper cells (Jiang and Chess 2000) (Figure 5). This CD8αβ$^+$ αβ T-cell response, which can likewise be elicited by irrelevant cells co-transfected with the Qa-1 and TCR Vβ8 chain genes, results in the cytolysis of the CD4$^+$ T cell, thus downregulating the associated immune effector response.

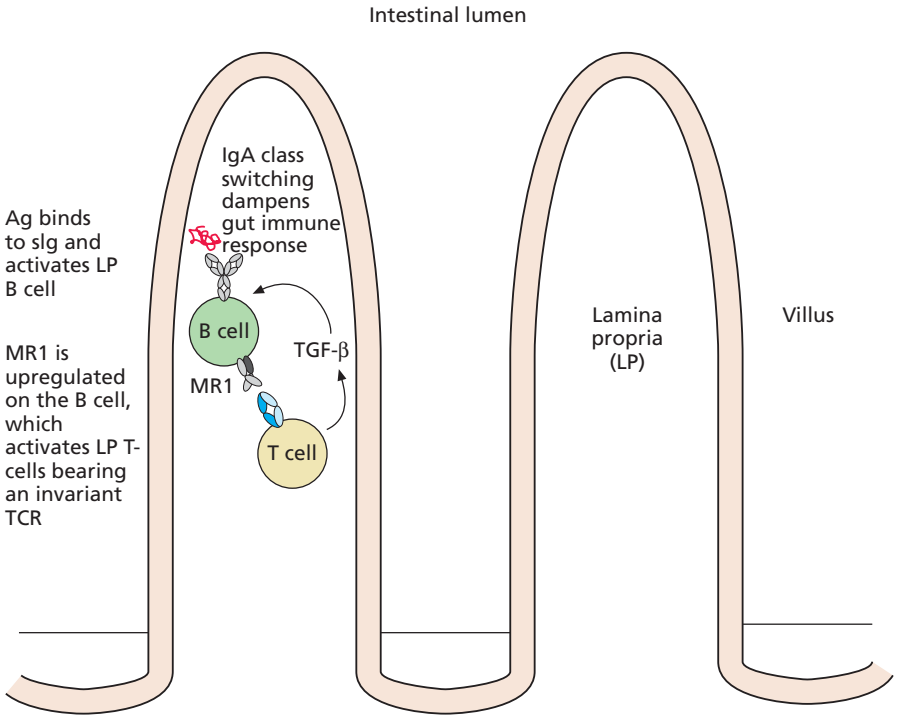

Figure 4 *MR1 is a ligand for a conserved population of lamina propria T cells. Expression of MR1 is upregulated on B cells on antigen binding to surface immunoglobulin. MR1 is recognized by T cells expressing an invariant Vα7Jα33 in humans (the homologous Vα19Jα33 in mice and cattle). On MR1 recognition, these T cells produce transforming growth factor β (TGFβ), which induces class switching to IgA, the appropriate isotype for the intestine; as well as preventing hyperactivation of the gut immune system. Ag, antigen; slg, surface immunoglobulin.*

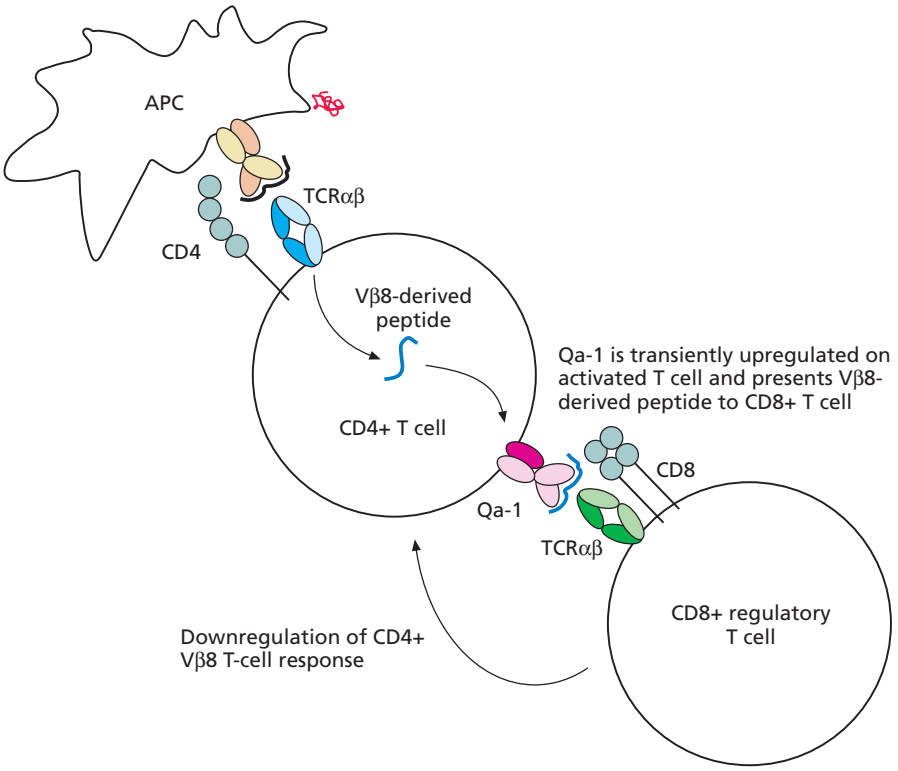

Figure 5 *Recognition by regulatory $CD8^+$ T cells of T-cell receptor (TCR)-derived peptides presented on Qa-1. Activated $CD4^+$ T cells transiently upregulate the nonclassic MHC class I molecule Qa-1, which presents peptides derived from the TCR Vβ8 chain. Qa-1 peptide complexes are recognized by $CD8^+$ regulatory T cells which downregulate the CD4 T-cell response. APC, antigen-presenting cell.*

Evidence that $CD8^+$ cytolytic T cells downregulate immune responses to self and to foreign antigens has been presented in many experimental systems for many years, e.g. mice induced to develop experimental allergic encephalomyelitis (in many regards, an animal model for multiple sclerosis (MS)) by immunization with myelin basic protein peptides conventionally show marked periods of disease remission, reminiscent of those that characterize MS and other autoimmune diseases in humans. These are eradicated by either antibody-mediated, or genetic depletion of, $CD8^+$ T cells, leading to unrelenting disease progression (Jiang et al. 1992; Koh et al. 1992). The prospect that such $CD8^+$ T-cell-mediated regulation might target $CD4^+$ T cells in an antigen receptor-specific fashion was emphasized by the finding that the immune response to hen egg lysozyme is reduced in strains of mice that, paradoxically, have more TCR Vβ genes. This immune deficiency is rescued by depletion of $CD8^+$ T cells, indicating that the regulatory cells are targeting $CD4^+$ T cells that express particular TCR Vβ genes (Jiang and Chess 2000).

One would assume, from first principles, that the cytolysis of $CD4^+$ $TCR\alpha\beta^+$ T-helper cells must be carefully regulated. In this light, Qa-1 has some interesting properties. First, it is only expressed on $CD4^+$ T cells after activation and, second, its expression is transient, thereby limiting the potential for regulation to a short window. Third, Qa-1 presenting leader peptides of conventional MHC class I molecules (Qdm) in addition engages an NKG2A/CD94 NK inhibitory receptor that is commonly expressed on activated $CD8^+$ T cells (Aldrich et al. 1994). The same is true for HLA-E, in humans. Thus, one might envision that, when a $CD4^+$ T cell expresses an excess of Qa-1.Qdm over Qa-1.TCR, the regulatory $CD8^+$ T cell is inhibited, whereas, when Qa-1.TCR is in excess, it is activated to target the $CD4^+$ T cell. Interestingly, immune regulation by $CD8^+$ T cells seems primarily to target $CD4^+$ Th1 cells rather than $CD4^+$ Th2 cells. The opposite has been claimed for the *fas*-mediated downregulation of autoreactive Th2 cells by systemic γδ cells (see above).

Unconventional peptide-reactive αβ T cells

Contemporary genomics analyses have revealed an increasing number of unconventional, MHC class 1B genes that are candidate ligands for further unconventional T-cell reactivities. One such reactivity is the αβ T-cell response to bacterial *N*-formylated peptides (Nfp), presented by H2-M3. As the initiator methionine groups in eukaryotic proteins are very rarely *N*-formylated, the recognition of Nfp might be regarded as a form of pathogen-associated molecular pattern recognition.

H2-M3 Nfp-reactive cells have been described in mice infected with *Mycobacterium tuberculosis* and *Listeria monocytogenes* and they may form a part of the T-cell response to a broad spectrum of bacteria. In *Listeria*-infected mice, multivalent cell-staining reagents comprising H2-M3 Nfp tetramers detected reactive αβ T cells early in the response, before the clonal expansion of conventional, MHC-peptide reactive αβ T cells. Consistent with this, the cells constitutively display markers of activation (e.g. $CD44^{hi}$). Two additional aspects of the tetramer-reactive cells are reminiscent of other unconventional T cells: (1) they have cytolytic and Th1 effector potential; and (2) they contribute substantially to primary responses, but, after secondary infection, their contribution is eclipsed by the effector responses of conventional $CD8\alpha\beta^+$ αβ T cells (Kerksiek et al. 1999). Also complying with the hypothesis that unconventional T cells differ from conventional T cells in their selection during development, it was recently shown that the progenitors of H2-M3 Nfp-reactive cells will positively select on autologous MHC class Ib antigens expressed in the thymus by hemopoietic cells, and that, contingent upon this, the cells immediately acquire an activated phenotype before thymic emigration (Urdahl et al. 2002).

Unconventional 'β-only' T cells

When a mutation was experimentally introduced into the mouse TCRα chain, by gene-by-gene knockout technology, a small population of peripheral, $CD4^+$ $TCR\beta^+$ cells was found in the resultant mice (Mombaerts et al. 1992). The potential for TCR β chain expression in the absence of TCRα exists via the formation of either TCRβ/β homodimers, or a complex of TCRβ with an alternately spliced product of the pre-Tα chain which can ordinarily pair with TCRβ during thymocyte development (Barber et al. 1998). As for other nonconventional T cells, these 'β-only' cells have potent Th1 activity and are in part responsible for pathogen-responsive bowel inflammations that develop in $TCR\alpha^{-/-}$ mice but not in $TCR\beta^{-/-}$ mice, which would lack $TCR\beta^{+\alpha-}$ cells.

Naturally, β-only cells have generally been regarded as an idiosyncrasy of $TCR\alpha^{-/-}$ mice, but their existence in normal animals should not be discounted. In thymocyte development, TCRβ-gene rearrangement precedes TCRα-gene rearrangement and the formal possibility therefore exists for cells that do not productively rearrange either TCRα-chain allele to mature as β-only cells. Although such cells would be thought unlikely to receive essential signals for positive selection on MHC, the fact that such cells are present in the periphery of $TCR\alpha^{-/-}$ mice clearly indicates the potential for some 'β-only cells' to mature. Given their functional potency, particularly their capacity to respond to microbial antigens, their existence in humans needs to be more thoroughly tested.

Regulatory CD4$^+$ CD25$^+$ αβ T cells: putative unconventional T cells

The diversity of unconventional T cells that has been considered in this chapter provokes the concept that unconventional T cells are not particularly rare, and that there may be other sets of T cells that are currently poorly understood, which may ultimately be assigned as unconventional. In this regard, much attention has recently been paid to a set of immunosuppressive T cells that can be found in mice and humans within the CD4$^+$CD25^{hi} subset. Although these markers alone are insufficient to identify a pure population of regulatory T cells (e.g. they also identify activated effector cells), they identify a subset of cells in the thymus that seemingly acquires an activated phenotype immediately on maturation. Perinatal thymectomy in certain strains of mice (e.g. Balb/c) selectively ablates such cells, provoking spontaneous, multiorgan, autoimmune disease. There remains much to learn about these regulatory cells, and there is a high likelihood that they are heterogeneous in phenotype. Nevertheless, evidence is gathering that at least some of them may comply with the operating definitions of unconventional T cells proposed at the beginning of this chapter. Specifically: their antigen specificity may be primarily selfreactive, not necessarily restricted to conventional MHC; their development, as stated, seems to be distinct from that of conventional αβ T cells; their recirculation patterns are ill-defined but evidence suggests that they may function primarily within tissues; and their potential to contribute to antigen-specific memory is also as yet unclear. The potential that such cells, with proven capacity to regulate immune responses in vivo would be assigned to the unconventional T-cell compartment further highlights the prudence of paying greater attention to the representation of unconventional T-cell subsets in health and disease.

Even long after the characterization of immunoglobulins and B-cell receptors, the molecular basis of antigen recognition by T cells has remained a major enigma for immunologists. Both the exquisite antigen specificity of T cells and their ability to mount memory responses suggested that, as with B cells, T cells recognized antigens through structurally diverse and clonally distributed receptors, then referred to as T-cell receptors (TCR). However, the unsuccessful attempts to identify idiotypic determinants shared by antibodies and TCRs and the fundamental difference between B-cell and T-cell antigen recognition processes, unveiled by the work of Zinkernagel and Doherty, fostered intensive debates in the 1970s about the TCR nature and structure. Addressing this issue turned out to be particularly challenging but was finally settled in the 1980s with the molecular characterization of the TCR genes. During the last decade, biophysical studies of TCR–pMHC (peptide major histocompatibility complex) interactions and structural analyses of trimolecular TCR–peptide–MHC complexes have brought insights into the fine mechanism of TCR recognition and T-cell activation, which are now viewed as dynamic processes relying on TCR conformational fits and complex interplays between immune receptors and signaling molecules within specialized supramolecular arrangements.

ISOLATION OF T-CELL RECEPTORS: AN HISTORICAL OVERVIEW

In several early 1970s studies, Zinkernagel and Doherty demonstrated that T-cell recognition of virally infected cells requires both viral antigens and expression of self-major histocompatibility complex (MHC) molecules by infected cells (Zinkernagel and Doherty 1974). By analyzing the responses of hybridomas obtained by fusion of T cells with distinct antigen and MHC specificities, Kappler and Marrack's group then showed, in agreement with the so-called 'altered self-model', that this 'self-MHC restriction' involves a single receptor that is able to recognize self-MHC molecules modified by or complexed to the antigen (Kappler et al. 1981). The first hints at the TCR structure were obtained by Allison and colleagues, who generated antisera specific to surface receptors expressed by restricted sets of T-cell clones and demonstrated the heterodimeric nature of these 'clonotypic' receptors (McIntyre and Allison 1983). Several groups showed later on that these heterodimeric receptors, called TCR$\alpha\beta$, were tightly associated on the cell surface with a multimeric transduction complex called CD3 (for a review, see Clevers et al. 1988). Identification of the first TCR gene was achieved in 1984 by the groups of Davis and Mak (Hedrick et al. 1984; Yanagi et al. 1984). The elegant strategy designed by Davis and colleagues to isolate candidate TCR genes relied on

two main assumptions: first that the putative TCR genes should be specifically transcribed in T cells and, second, that as with immunoglobulin (Ig) genes, TCR genes should undergo somatic rearrangement. Thus they prepared complementary DNA (cDNA) from a T-cell clone and enriched for T-cell-specific genes by removing the cDNA species that hybridized to B-cell messenger RNA (mRNA). The remaining cDNAs were then used as probes to detect, by Southern blot analysis, genes with patterns that are specifically modified in mature T cells. Following this approach, this group isolated a cDNA showing significant sequence homology with Ig genes, which turned out to encode the TCRβ chain. While looking for the missing α-chain gene (which was isolated a few months later), Tonegawa and colleagues fortuitously identified, in the same year, another gene specifically rearranged in T cells called γ (Saito et al. 1984). Discovery of this 'orphan' gene suggested the existence of new class of TCR, which was totally unexpected from previous immunological studies, and the existence of which remained elusive during the following 2 years. Postulating that, as with the αβ TCR, the γ gene product should form a TCR associated with the CD3 complex, Brenner and colleagues used CD3-specific monoclonal antibodies to immunoprecipitate a new heterodimeric receptor expressed on a distinct set of T cells (Brenner et al. 1986). The TCR gene coding for the missing δ chain was finally identified in 1987 by Davis's group (Chien et al. 1987).

GENOMIC ORGANIZATION AND SOURCE OF TCR DIVERSITY

As for Ig genes, functional TCR genes are generated through somatic recombination of gene segments that are originally separated on the chromosome. This rearrangement process, which is tightly controlled in a lineage- and stage-specific manner, allows the production of myriads of distinct receptors. Similar to antibodies, TCR diversity originates both from the combinatorial usage of VDJ gene segments picked out from a repertoire of distinct elements and from extensive sequence modifications of the rearranged VDJ genes which are mediated by the recombination machinery.

Organization of TCR loci

There are four TCR gene loci in the germline DNA, each comprising arrays of distinct V, J, and in some cases D elements. V elements can be grouped into families, which correspond by convention to sets of V genes with nucleotide sequences that exhibit more than 75 percent homology. V-gene segments have two exons, D and J segments a single exon, and C-gene segments three to five exons. A schematic representation of the organization of TCR loci is represented in Figure 1. Detailed description of the VDJ sequences and nomenclatures can be obtained from the ImmunoGenetics database (www.imgt.cnusc.fr:8104).

THE TCRβ LOCUS

The TCRβ locus is located on chromosome 6 in the mouse and 7 in humans. It encompasses a region of grossly 600 kb in humans. All Vβ genes are clustered in the same chromosomal region except *BV30*, which is located downstream of the Cβ2 element and in opposite transcriptional orientation. In humans, there are 67 Vβ elements (of which 41–47 are functional) clustered into 32 Vβ families (Rowen et al. 1996). The 3′ part of the TCRβ locus corresponds to a duplication of an ancestral region comprising one Dβ segment, six functional Jβ segments, and a Cβ gene. The two Cβ genes differ by four amino

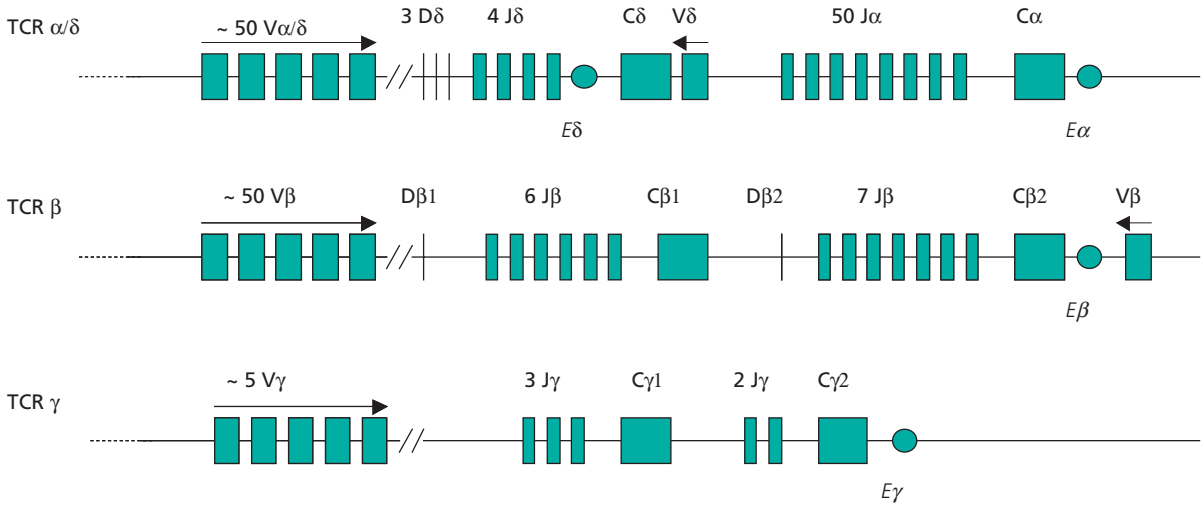

Figure 1 *Genomic organization of human T-cell receptor (TCR) gene loci. See the text for details. The numbers mentioned in the figure take into account functional V- and J-gene segments only. V-gene transcriptional orientation is indicated by arrows. Circles correspond to enhancer elements.*

acids only, and appear functionally equivalent. In this regard, unlike Ig genes, rearranged TCR genes do not undergo isotype switching (which consists of replacing the constant region of a rearranged Ig gene by another constant region, generally endowed with distinct functional properties). A β enhancer, which plays a key role in the control of TCRβ locus transcription and rearrangement (see 'Control of TCR gene assembly' below), is located between the Cβ2 element and the downstream BV30 element (Gottschalk and Leiden 1990).

THE TCRα/δ LOCUS

The TCRαδ locus is located on chromosome 14 in rodents and humans, and encompasses a chromosomal region of roughly 1 Mb. It comprises 45–47 functional Vα segments grouped into 41 families in humans. There are 50 functional Jα elements and a single Cα gene. The TCRδ locus is located within the α locus, between the Vα and Jα segments. This peculiar location has important implications because any VJα rearrangement leads to deletion of the δ locus. Together with transcriptional regulation processes detailed below, this mechanism prevents co-expression of α and δ chains and ensures mutual expression of αβ and γδ TCR in a given T cell. The human δ locus comprises three Dδ segments (two in rodents), four Jδ segments (two in rodents), and one Cδ segment. The Vδ and Vα elements are interspersed, which theoretically permits their rearrangement to either DJδ or Jα elements. Although this happens to be the case for some V segments (Miossec et al. 1990), the sets of Vα/δ elements used to form αβ and γδ TCR are generally distinct and only eight Vα/δ elements are used to a significant extent by γδ cells. Among these, one Vδ segment (DV3) is located between the Cδ and Jα elements, in an opposite transcriptional orientation. The rules governing usage of V-gene segments by either the α or δ chain are still unclear but presumably complex. It is likely that both cell-selection processes and locus accessibility constraints contribute to the biased expression of particular Vδ regions by most γδ T cells (see below). Several regulatory sequences controlling TCRα/δ locus transcription and rearrangement have been identified: a TCRα enhancer located downstream to the Cα gene (Ho et al. 1989), the T-early α (TEA) element (which controls rearrangements involving the most upstream Jα segments) between the Cδ and Jα elements (de Chasseval and De Villartay 1993; Wilson et al. 1996), a TCRα silencer (called BEAD-1 for blocking element α–δ 1) immediately upstream from TEA (Zhong and Krangel 1997) and a TCRδ enhancer upstream from the Cδ gene (Redondo et al. 1990).

THE TCRγ LOCUS

Located on chromosome 13 in the mouse and 7 in humans, the γ locus is spread over 160 kb in humans and 200 kb in the mouse. Its genomic organization significantly differs between these two species. In the mouse, there are four clusters presumably resulting from duplication events, which each comprise a single J and C segment together with one to four Vγ segments. A γ enhancer is found downstream to Cγ1 and Cγ3 and upstream from Cγ2 (Vernooij et al. 1993). The human γ locus comprises 11–14 Vγ segments (of which four to six are functional) grouped into four families, and two downstream clusters of J- and C-gene segments (Lefranc and Rabbitts 1989). A γ enhancer and two silencers are found downstream to Cγ2 (Lefranc and Alexandre 1995).

TCR rearrangements

Each TCR chain is encoded by multiple VDJ gene segments which are originally separated on the chromosome. During T-cell development these elements are joined to form a single exon coding for the variable domain of each recognition subunit. The V domain of TCRα and γ chains, like Ig light chains, is encoded by V and J elements, whereas the V domain of TCRβ and δ chains, like Ig heavy chains, is encoded by V, D, and J elements. V(D)J recombination is initiated by recognition and cleavage of double-stranded DNA at conserved sites, named recombination signal sequences (RSS), that immediately flank the V, D, and J elements (Tonegawa 1983). The RSSs are highly conserved in TCR and Ig genes, and each consist of a palindromic 7-base-pair (bp) sequence (consensus 5′-CACAGTG) and an A/T-rich 9-bp sequence (consensus 5′-ACAAAAACC), separated by a poorly conserved spacer, the length of which is either 12 ∓ 1 or 23 ∓ 1 bp (Figure 2a). As for Ig genes, recombination between two TCR-gene segments follows the 12/23 rule, i.e. recombination occurs only between an RSS with a 12-bp spacer and one with a 23-bp spacer (Early et al. 1980) (Figure 2b). The enzymatic machinery mediating TCR and Ig gene rearrangements involves both lymphoid cell-specific recombinases called RAG1 and RAG2 (Schatz et al. 1989; Oettinger et al. 1990), and ubiquitous enzymes of the DNA-repair machinery (for recent reviews, see Grawunder et al. 1998; Fugmann et al. 2000). The recombination process is outlined below and depicted in Figure 3.

V(D)J assembly is initiated by the recognition of the 12-bp and 23-bp RSSs by the RAG proteins, which bring the RSS into close juxtaposition (synapsis) (step no. 1). This step involves two ubiquitous enzymes promoting DNA bending (called high mobility group (HMG)-1 and -2 proteins), which stabilize interactions between RAG proteins and RSSs and ensure the 12/23 rule (Van Gent et al. 1997). RAG proteins then introduce a precise nick on one DNA strand between the RSSs and its flanking element, rapidly followed by cleavage of the other strand (step no. 2). At the end of this first phase, the

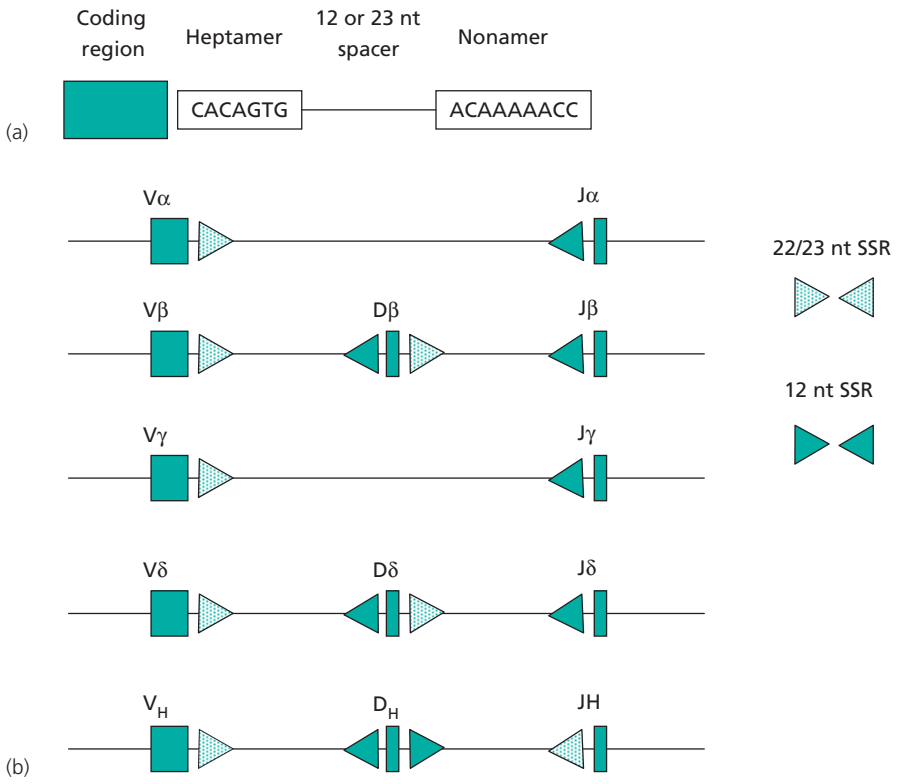

Figure 2 *Structure of recombination signal sequences and distribution within the T-cell receptor (TCR) and immunoglobulin (Ig) gene loci. See the text for details.*

recombinases catalyze by a transesterification mechanism both the generation of two open signal strands and the formation of a hairpin between the two open coding strands (McBlane et al. 1995).

The second phase of the recombination reaction is more complex and involves both the recombinases and a larger set of enzymes involved in the repair of DNA double-stranded breaks. The signal ends are joined

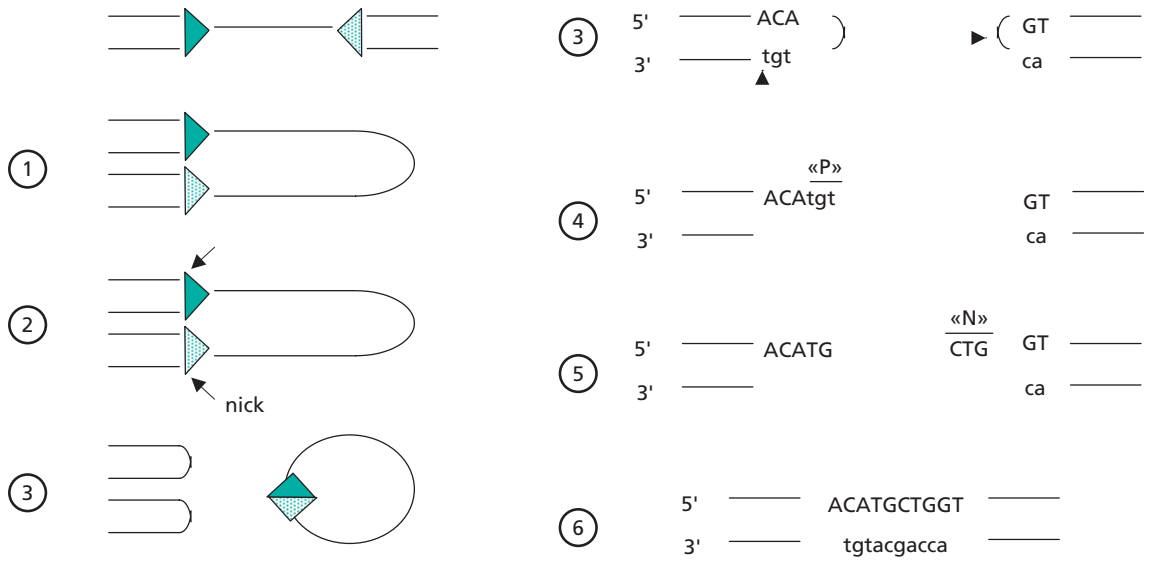

Figure 3 *The V(D)J gene recombination reaction. See the text for details. Dark and light triangles correspond to 12 bp and 23 bp recombination signal sequence (RSS). Step 1: synapsis. Step 2: nicking of the RSS. Step 3 (bottom left): generation of hairpins at the coding ends, formation of signal joints in excised circular DNA. Step 3 (up right): hairpin nicking resulting in nibbling of coding ends or addition of 'P' nucleotides (step 4). Step 5: addition of 'N' nucleotides. Step 6: filling and ligation of the coding joints.*

head to head, leading to formation of a 'signal joint' (step no. 3). This process is catalyzed by the RAG proteins and the ubiquitous HMG and Ku DNA-repair proteins (Agrawal and Schatz 1997). On the other side of the recombination complex, the hairpin formed between the two coding ends is opened through introduction of a nick, possibly catalyzed by the recombinases themselves (Shockett and Schatz 1999) (step no. 3). This nicking process is quite imprecise because it occurs at the tip of the hairpin, the coding strand, or the noncoding strand. This generates, respectively, full-length coding ends, deletions on the coding end, or addition of so-called palindromic (or 'P') nucleotides derived from the noncoding strand (Lafaille et al. 1989; Lieber 1991) (step no. 4). In mice deficient for the catalytic subunit of DNA–protein kinase (DNA-PKcs) or for Ku proteins, there is an almost complete abrogation of T- and B-cell production, accompanied by accumulation of uncleaved hairpin coding ends in developing lymphocytes (Lieber et al. 1988; Zhu et al. 1996). This indicates that DNA-PKcs and Ku proteins are both required for RAG-mediated hairpin opening, and probably act by stabilizing interactions between the RAG protein and the coding end-complex. After hairpin opening, the coding ends may undergo an exonucleolytic processing controlled in part by the DNA-PK, which results in significant nibbling of the rearranged VDJ elements. Variable numbers of so-called 'N' nucleotides may be added in a template-independent fashion at the coding ends (step no. 5). This reaction is catalyzed by a lymphoid cell-specific polymerase called terminal deoxynucleotidyl transferase (TdT) (Komori et al. 1993), which acts in conjunction with DNA-PKcs and Ku proteins (Bogue et al. 1997). As for B cells, TdT expression is repressed during embryonic life, resulting in lack of 'N' additions within the rearranged TCR genes produced at that stage. The physiological significance of the regulated expression of TdT during development is still unclear. As suggested by analysis of fetal γδ T-cell development in in vitro thymic organ cultures, TdT repression may favor generation of particular fetal T-cell subsets with conserved TCR and possibly mandatory functions (Ikuta et al. 1990). Alternately lack of TdT activity may prevent development of particular lymphoid subsets which might be deleterious during fetal life.

In the last step of the recombination reaction, the sense and antisense strands of the processed coding ends tend to align along short homologous regions of two to three nucleotides (homology-guided recombination) (Feeney 1992). As discussed earlier, the homology-guided recombination process favors the production of TCR with particular junctional sequences, which may represent a significant fraction of the fetal TCR repertoire (Itohara et al. 1993). The double-stranded DNA junctions are reconstituted through the combined action of yet undefined polymerases and nucleases (step no. 6). Final ligation of the coding strands is performed by the ligase IV/XRCC4 complex, presumably recruited by the Ku proteins (Nick McElhinny et al. 2000).

Modalities of TCR recombination

As for Ig genes, the intervening DNA sequence separating the rearranged TCR gene segments has two possible outcomes (Figure 4). When the rearrangement involves

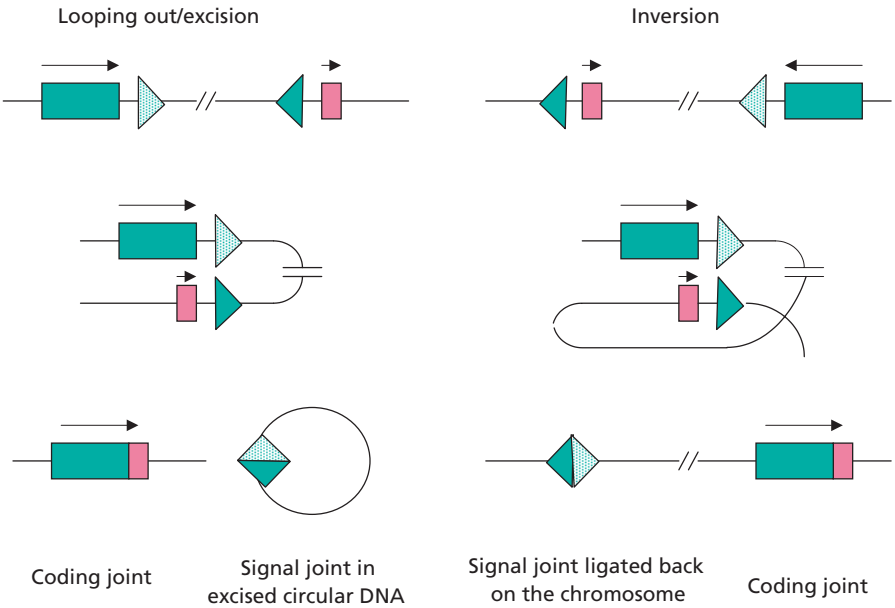

Figure 4 *Recombination modalities. See the text for details. Rectangles: coding regions. Triangles: recombination signal sequences (RSSs). Arrows: transcriptional orientation.*

elements in the same transcriptional orientation, which is the classic situation, the intervening DNA stretch between the rearranged gene segments is removed in the form of circular excision products, generated on head-to-head ligation of the RSS (looping out/excision model) (Okazaki et al. 1997). These circular DNAs are specifically found within developing lymphocytes and, thus, can be used as markers to follow T-cell regeneration, e.g. in HIV patients and bone marrow recipients. When the rearrangement involves gene segments in opposite transcriptional orientation (as is the case for the most downstream V elements in the TCRβ and TCRδ loci), the intervening DNA is ligated back and translocated on the chromosome through a chromosomal inversion mechanism (Malissen et al. 1986).

Although recombination events classically involve gene segments belonging to the same locus, they sometimes occur between distinct TCR loci, TCR and Ig loci, or TCR or Ig loci and other genomic elements. These interlocus recombinations or 'trans-rearrangements' are mediated through recognition of classic RSS and/or related or cryptic RSS motifs that are present throughout the genome. The peculiar configuration of the TCRα/δ locus naturally favors rearrangements of a given Vα/δ element to either DJδ or Jα segments (Miossec et al. 1990). Rearrangements between human TCRβ and TCRγ loci, which are both located on chromosome 7 but in distinct regions and in opposite orientations, may occur at high frequencies in T cells from healthy donors and patients with ataxia telangiectasia (Lipkowitz et al. 1990). These trans-rearrangements lead to expression of functional Vγ(Dβ)JβCβ chains that pair with classic TCRα chains, and thus significantly contribute to TCR repertoire diversification (Davodeau et al. 1994; Retière et al. 1999). Finally some lymphoid tumors may originate from illegitimate recombinations between an RSS within a TCR or Ig locus and a cryptic signal sequence close to an oncogene, e.g. Burkitt's lymphomas result from rearrangements between the protooncogene *c-myc* and RSS flanking Jα segments, leading to constitutive expression of *c-myc* expression under the control of the α enhancer (Bernard et al. 1988).

Sources of TCR diversity

Although the number of germline V(D)J elements is much lower in TCRs than in Ig loci, several mechanisms operate during TCR gene assembly to yield a high degree of diversity within the junctional regions of the rearranged VJ or VDJ genes.

COMBINATORIAL DIVERSITY

TCR combinatorial diversity is determined by the number of random V(D)J combinations yielding an αβ or γδ TCR. Although lower than Ig, the combinatorial diversity of αβ TCR appears to be much higher than that of γδ TCR. The random assembly of TCR VJα and VDJβ genes can generate, grossly, 2500 (i.e. 50×50) and 1200 (i.e. $50 \times 2 \times 12$) possible combinations respectively. Considering a random association of α and β chains, this yields up to 3×10^6 distinct TCRs. By contrast, the total number of VJγ/VDJδ combinations is around 3000 only (i.e. $(6 \times 5) \times (10 \times 3 \times 4)$) in humans. An additional source of combinatorial diversity is provided by the peculiar arrangement of the 12- and 23-bp RSSs in TCR genes which permits, unlike Ig genes, joining of several D-gene segments in tandem (see Figure 2b). Such joining events, yielding VDDJ or even VDDDJ junctions, are frequently seen within rearranged TCRδ genes and drastically broaden the junctional length distribution of the δ chains (Chien et al. 1996).

JUNCTIONAL DIVERSITY

VDJ assembly is associated with important modifications of the coding ends of the rearranged segments (see Figure 3). First, the imprecise cleavage of hairpin coding ends may lead to either 'P' nucleotide additions or nibbling of V(D)J sequences. Second, further VDJ nibbling may occur at a later stage of the recombination reaction by exonucleolytic processing. Third, addition of variable numbers of 'N' nucleotides by TdT may further increase junctional sequence diversity. All these mechanisms operate in both TCR and Ig gene rearrangements. However, although 'N' additions occur in rearranged Ig heavy chain genes only, they are observed in all rearranged TCR genes. Reading frame changes resulting from nucleotide addition and trimming may generate nonproductive rearrangements but, in the case of VDJ rearrangements, they may also generate new junctional sequences encoded by alternate reading frames. In this regard, unlike D_H segments, both the Dβ and Dδ segments can be read in all three reading frames. Altogether nucleotide addition and nibbling at the V(D)J joints generate an enormous diversity in these regions. Considering that up to six nucleotides can be added at each junction, the number of distinct junctional sequences that can be produced in the order of 10^7 to 10^{11}.

SOMATIC HYPERMUTATION

In B cells, additional diversity is generated in the rearranged V(D)J genes by somatic hypermutation (see Antibodies and B Lymphocytes). By contrast, TCR genes do not undergo somatic hypermutation. This probably ensures that the T-cell repertoire is not modified after its thymic selection and avoids generation of cells with unwanted self-reactivity.

FACTORS RESTRICTING TCR DIVERSITY

The combined effects of combinatorial and junctional diversification processes theoretically permit the production of up to 10^{16} distinct TCRs in a given individual. However, this number is probably largely overestimated for several reasons. Assembly of V(D)J segments is not

random because, in general, not all gene segments are equally accessible to the recombination machinery at a given time point. In particular the most downstream V and upstream J elements tend to be rearranged first during ontogeny (Thompson et al. 1990), probably reflecting progressive 'opening' of the TCR locus under the control of proximal *cis*-acting elements. This is also illustrated by the programmed rearrangement of different sets of VDJ gene segments at particular T-cell developmental stages (Goldman et al. 1993; Itohara et al. 1993), which favors generation of distinct waves of γδ TCR with restricted combinations of VJγ and VDJδ elements. Finally, both the repression of TdT activity during fetal life and homology-guided recombination further restrict the diversity of the fetal repertoire, which is sometimes dominated by few 'canonical' TCR sequences (Itohara et al. 1993).

CONTROL OF TCR GENE ASSEMBLY

Assembly of TCR and Ig V(D)J segments is regulated in a tissue-, lineage-, and stage-specific fashion. The restricted expression of RAG proteins in lymphoid cells at a particular stage of their development confers both the tissue- and stage-specificity of the recombination process. In addition, the restricted activation of Ig and TCR gene rearrangements in respectively T and B cells is controlled by *cis*- and *trans*-acting elements that regulate the 'accessibility' of TCR and Ig gene loci to the recombinases (Sleckman et al. 1996).

Regulation of TCR gene assembly during T-cell development

T-cell development is a highly complex and ordered epigenetic process that allows efficient generation and highly restricted TCR expression in the appropriate cell lineage, as well as selection of TCR with 'useful' (i.e. self-MHC-restricted) and 'harmless' (i.e. nonself-reactive) specificities. Importantly a tight control of the accessibility of the various TCR loci to the recombination machinery, which is transiently activated during the pre-T-cell stage, leads to a highly ordered activation of TCR rearrangements in the developing T cell (Figure 5) and early commitment of precursor cells to either the αβ or the γδ lineage (Figure 6).

INITIATION OF TCR REARRANGEMENTS AND PRE-TCR FORMATION

Intrathymic T-cell maturation can be subdivided into discrete developmental stages characterized by a particular TCR rearrangement status and phenotypic profile (Shortman and Wu 1996). In the mouse the earliest precursors, which are CD4/CD8 double negative (DN), are further split into four subsets based on CD44 and CD25 expression. RAG protein expression is initiated in $CD44^+CD25^-$ (DN I) precursors (Wilson et al. 1994). VJγ, partial VDδ or DJδ and few complete VDJδ rearrangements are first detected at the $CD44^+CD25^+$ (DN II) stage (Livak et al. 1999). Most VJγ, VDJδ, and partial DJβ rearrangements take place during transition to the $CD44^-CD25^+$ (DN III) stage (Tourigny et al. 1997). Complete VDJβ rearrangements are initiated in $CD44^+CD25^+$ cells and are completed in $CD44^-CD25^-$ (DN IV) cells, where productive VDJβ rearrangements are primarily found. VJα rearrangements are first detected in $CD44^-CD25^-$ cells but mainly take place at the following $CD4^+CD8^+$ stage.

A similarly ordered rearrangement of TCRδ, γ, β, and α genes has been more recently documented in human thymocytes (Blom et al. 1999). The TCRβ chains, which are produced at a stage when the α locus is still in germline configuration, pair with a surrogate α chain called

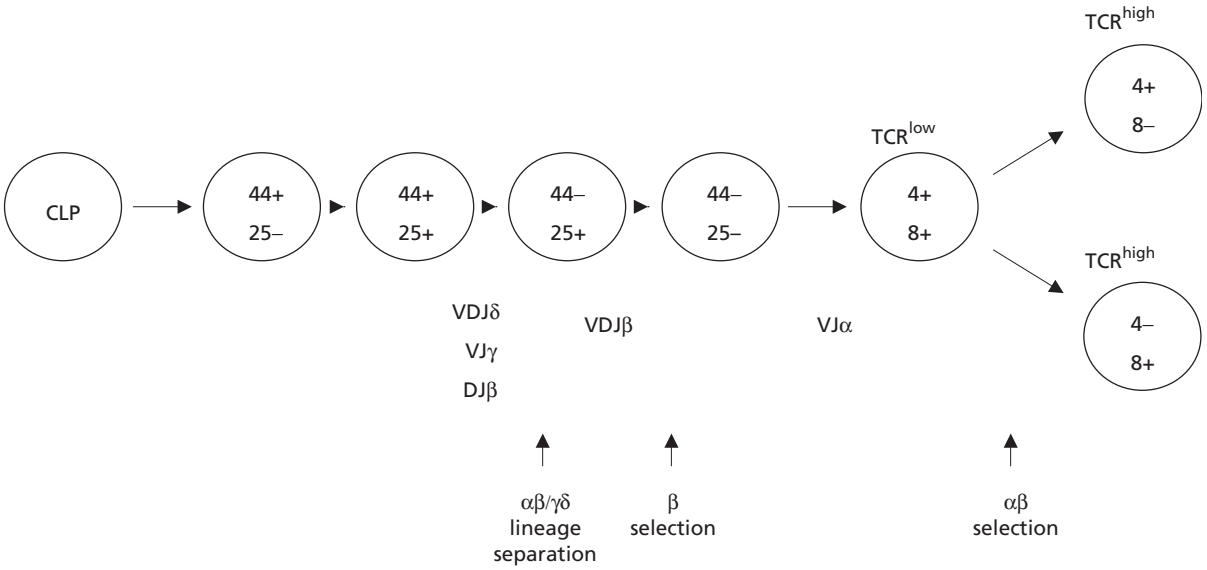

Figure 5 *Intrathymic development of murine T cells. See the text for details. CLP, common lymphoid progenitor.*

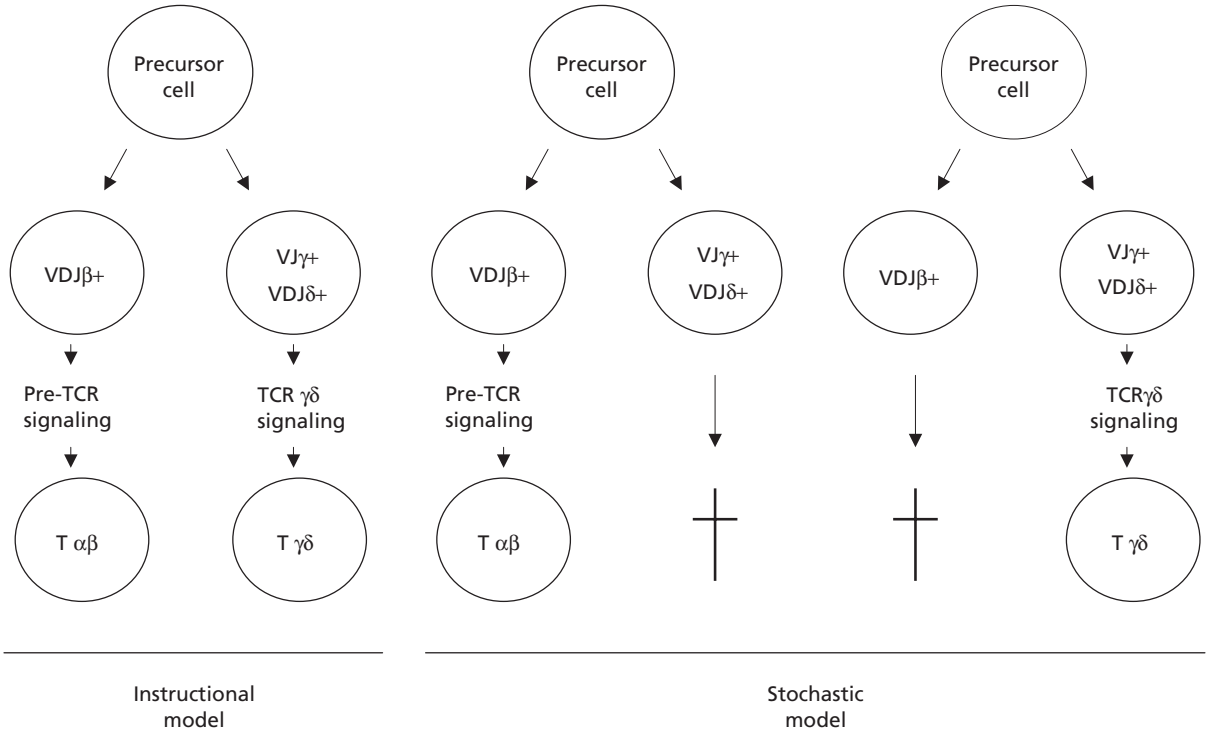

Figure 6 *Models of αβ/γδ lineage separation. See the text for details.*

pTα to form a 'pre-TCR' (Saint Ruf et al. 1994). The pTα is encoded by a non-rearranging gene, the expression of which is transiently switched on during T-cell development. It comprises a single Ig-like ectodomain, a transmembrane region with a positively charged amino acid, and a short intracytoplasmic region. Similar to the TCR, the pre-TCR is associated with a complex of CD3 subunits that mediates signal transduction (see 'TCR structure' below). Signaling through the CD3/pre-TCR complex induces transient but massive thymocyte proliferation, paralleled by rapid loss of CD25 and acquisition of CD4, CD8, CD2, CD5, and CD69 markers (Levelt et al. 1995). The mere expression of pre-TCR/CD3 complexes (i.e. without engagement by a putative thymic ligand) is probably sufficient to induce the transition from the DN to the $CD4^+CD8^+$ stage (Irving et al. 1998). Signaling through the pre-TCR (also called 'β selection') represents a key developmental checkpoint, which permits selective expansion and subsequent maturation of T-cell precursors that have generated a functional TCRβ chain. Consistent with a such a critical role played by the pre-TCR, T-cell development is arrested at the $CD44^-CD25^+$ stage in mice deficient for the RAG, β, pTα, CD3γ, or CD3ϵ proteins (for a recent review, see Sebzda et al. 1999).

EXPRESSION AND INTRATHYMIC SELECTION OF αβ TCR

During the proliferation phase induced by pre-TCR signaling, recombinase activity is drastically reduced as a result of phosphorylation and accelerated degradation of the RAG2 protein (Lin and Desiderio 1994). Re-expression of RAG proteins at this stage seems to be controlled by specific *cis*-acting elements located upstream of the RAG2 promoter (Yu et al. 1999). RAG expression and 'opening' of the α loci allow VJα rearrangements and expression of αβ TCR, which then undergo intrathymic selection. According to the widely accepted affinity/avidity model, the outcome of the $CD4^+CD8^+$ thymocyte will depend on the strength of the avidity signal delivered by its TCR, which integrates both the affinity of the TCR for self-pMHC complexes and the number or density of TCR/pMHC interactions. Below a given avidity threshold, the thymocyte dies by neglect. Above it, the thymocyte is positively selected, i.e. it receives a maturation signal that triggers RAG protein shut-off, TCR upregulation, and modulation of either CD4 or CD8 co-receptors. Finally thymocytes showing very high avidity for self-pMHC are negatively selected, i.e. they receive an apoptotic or inactivating signal leading to their deletion or anergization. Altogether these thymic selection processes, while avoiding production of self-reactive T cells, allow generation of a functional T-cell repertoire with significant affinity for self-MHC (Sebzda et al. 1999).

TCR ALLELIC EXCLUSION

As a result of their diploid nature, T-cell precursors can produce up to four distinct αβ TCRs. T-cell clones

generally express a single β chain, which indicates that, similar to Ig genes, the TCRβ locus exhibits allelic exclusion (for a review, see Malissen et al. 1992). Endogenous VDJβ, but not DJβ, gene rearrangements are inhibited in mice expressing a functional TCRβ transgene, suggesting a tight exclusion mechanism whereby generation of a productive VDJβ rearrangement blocks subsequent V to DJβ rearrangement on the other allele (Uematsu et al. 1988). The increased frequency of precursors carrying two complete VDJβ rearrangements in pTα-deficient mice suggests a key implication of the pre-TCR in the negative feedback loop leading to allelic exclusion (Aifantis et al. 1997). Therefore TCRβ exclusion can be explained by the fact that, in the presence of pTα, any functional β chain, irrespective of its specificity, forms a pre-TCR that systematically generates an allelic exclusion signal. Its precise mechanism is still unclear but probably relies on both a transient reduction of the recombinase activity during the proliferation phase that follows pre-TCR signaling and concomitant inhibition of β locus accessibility to recombinases (Sleckman et al. 1996). Unlike β chains, expression of two distinct α chains is quite frequent within mature T-cell clones, indicating a less stringent rearrangement control in the α loci (Padovan et al. 1993). Accordingly, T cells from mice expressing a functional TCRα transgene frequently express endogenous α genes (Borgulya et al. 1992). TCRα allelic inclusion is explained by the fact that the TCRα rearrangement arrest signal, which leads to recombinase shut off in the developing thymocyte, is only generated after TCR engagement by a positively selecting ligand (Turka et al. 1991). Therefore in a T cell that expresses two distinct αβ TCRs, only one is likely to be functional, i.e. restricted by self-MHC molecules.

αβ/γδ LINEAGE SEPARATION

Targeted inactivation of pTα or β genes in the mouse abrogates development of αβ T cells and drastically inhibits production of double-positive thymocytes. By contrast it has no effect on the generation of γδ T cells, which indicates that γδ T-cell development does not require a pre-TCR (Fehling et al. 1995). Accordingly, unlike β and α genes, activation of γ and δ gene rearrangements occurs concomitantly during development, suggesting that γδ T cells do not undergo a 'preselection' process. αβ and γδ T cells derive from a common progenitor and probably diverge during the transition from the DN III to the DN IV stage (Mertsching et al. 1997). Analyses of the TCR rearrangement status of developing and mature T cells suggest several models of αβ/γδ lineage separation (see Figure 6). According to the 'stochastic' model, precursor cells are precommitted to one or the other lineage before TCR rearrangement and expression. This assumption is supported by studies documenting transcriptional silencing of pTα or α genes in γδ T-cell precursors (Capone et al. 1993; Mertsching et al. 1997) or silencing of some γ genes in αβ T cells (Ishida et al. 1990).

'Instructive' models postulate that the fate of a given precursor is determined by the expressed TCR, i.e. generation of productive γ and δ rearrangements and subsequent expression of γδ TCR engage the precursor toward the γδ lineage, whereas generation of a productive β rearrangement and pre-TCR expression engage the precursor toward the αβ lineage. Among these last models, the 'separate lineage' model proposes that αβ T cells primarily develop from precursor cells that have failed to produce a functional γδ TCR, assuming that VJγ and VDJδ rearrangements precede VDJβ rearrangements during ontogeny (Dudley et al. 1995). According to the 'competitive' model, which seems better supported by recent studies (Livak et al. 1995; Aifantis et al. 1998), VJγ, VDJδ, and VDJβ gene rearrangements take place concomitantly in the same precursor cell, the fate of which is determined by the TCR or pre-TCR that is first produced. Actually, none of these models provides fully satisfactory explanations for all the experimental data obtained so far. It seems likely that the modalities of αβ/γδ lineage separation differ from one subset to another and are possibly determined by a mix of stochastic and instructive events, as is the case for the differentiation of $CD4^+CD8^+$ thymocytes into either $CD4^+CD8^-$ or $CD4^-CD8^+$ cells (see $CD4^+$ T lymphocytes and The role of CD8 T cells in the control of infectious disease and malignancies).

Factors controlling TCR accessibility to recombinases

Expression of transfected RAG proteins in nonlymphoid cells leads to rearrangement of plasmid-like recombination substrates, but not to endogenous TCR or Ig genes (Schatz et al. 1992). Thus, unlike developing lymphocytes, the antigen-receptor genes of nonlymphoid cells are not accessible to the recombination machinery. The fact the Ig and TCR gene rearrangements are restricted respectively to B and T cells suggests differential control of the accessibility of these antigen receptor loci in the corresponding lymphoid precursors (Sleckman et al. 1996). The mechanisms controlling TCR locus accessibility are not completely understood. VDJ recombination closely correlates with changes in chromatin structure, changes in gene methylation status, and transcriptional activation of TCR (or Ig) gene loci (Sleckman et al. 1996). Active transcription of germline V segments coincides with their rearrangement, as clearly illustrated by analysis of the TCRγ locus, where production of germline Vγ transcripts tightly correlates with the ordered rearrangement of these segments during development (Goldman et al. 1993). Along this line analyses of transgenic recombination substrates suggest a key role played by *cis*-acting transcriptional

enhancer elements in regulating, in a tissue-, lineage- and stage-specific fashion, recombination of a given TCR or Ig gene locus, e.g. rearrangements of endogenous α genes occur at a later developmental stage than for endogenous β genes. Accordingly β transgenes carrying an α enhancer rearrange later than the same transgenes with a β enhancer, suggesting a direct role of enhancer elements in dictating the stage specificity of VDJ recombination (Capone et al. 1993). However, recombination and rearrangement are not always strictly correlated. In particular, deletion of the β enhancer inhibits both TCRβ transcription and rearrangements. However, RAG-mediated cleavage of VDJβ elements still occurs but ligation of the coding end is prevented. This suggests that the β enhancer regulates the late stages of the recombination reaction but to a lesser extent the locus accessibility to recombinases (Hempel et al. 1998).

Transcriptional regulation is mediated in part by interactions between *trans*-acting DNA-binding proteins with specific motifs in *cis*-acting promoter and enhancer elements. This process turns out to be particularly complex and involves the combinatorial action of several ubiquitous transcriptional factors (Ernst and Smale 1995). As a result of this complexity, it has not been possible yet to identify specific combinations of transcriptional factors able to regulate, in a lineage- or stage-specific fashion, TCR or Ig gene rearrangements, e.g. mutations in the binding sites for *c-myb* and CBF/PEBP2 transcription factors within the δ enhancer abrogate recombination of a TCRδ minilocus. However, replacement of the δ enhancer by a DNA fragment carrying both *c-myb* and CBF/PEBP2 sites does not restore recombination, indicating the need for additional factors for proper regulation of δ rearrangements (Lauzurica et al. 1997).

Besides transcriptional activation, occurrence of VDJ rearrangements is tightly associated with remodeling of chromatin structure, possibly under the direct control of TCR enhancers. In particular histone hyperacetylation and associated chromatin decondensation strongly correlate with activation and/or completion of VDJ rearrangements (McMurry and Krangel 2000). Gene methylation, which is associated with transcriptional silencing, also prevents TCR rearrangements (Hsieh and Lieber 1992). TCR locus demethylation, which is concomitant to VDJ recombination, seems again directly regulated by the enhancers (Kirillov et al. 1996).

Finally *cis*-acting elements blocking TCR accessibility have been identified in the TCRα and γ loci (Ishida et al. 1990). These 'silencers' may selectively repress, in either a stochastic or instructive manner recombination of a given locus in precursor cells committed to the reciprocal cell lineage (see 'Regulation of TCR gene assembly during T-cell development' above).

TCR STRUCTURE

Overall structure of the T-cell recognition complex

TCR CHAINS

αβ and γδ TCRs are expressed in a mutually exclusive fashion on T cells. In adult thymus, blood, spleen, and lymph nodes, the vast majority of T cells express αβ TCRs in rodents and primates. By contrast γδ T cells are greatly enriched in epithelial sites where they sometimes make up all $CD3^+$ T cells (see Unconventional T cells). The apparent molecular mass (M_r) of α and β chains, which are both glycosylated, is around 42–48 kDs (Clevers et al. 1988). The M_r of γ and δ chains ranges from 30 to 60 kDa and from 40 to 60 kDa, respectively. The isoelectric point of γ and β chains is basic and that of α and δ chains acidic. Each TCR chain possesses a short cytoplasmic tail, a hydrophobic transmembrane region and a large extracellular portion comprising two Ig-like domains, a variable and a constant domain which are respectively distal and proximal to the membrane (Figure 7).

As with Ig, the variable domain is encoded by two to three gene segments that form a single exon after somatic rearrangement (Figure 8). The amino-terminal part of the variable domain is encoded by the V-gene segment whereas its carboxy-terminal part is encoded by either a single J segment (for α and γ) or D and J segments (for β and δ chains). The length of the V region is around 75–95 amino acids, the J region 15 amino acids, and the D region 5 amino acids. The constant domain is encoded by a C gene comprising three to four exons. The first exon codes for the globular domain stabilized by an intrachain disulfide bond, which is slightly longer (125–135 amino acids for β) or shorter (85 amino acids for α) than the Ig domain (around 110 amino acids). The second exon codes for a 'connecting' region of six amino acids, which frequently comprises a cysteine involved in the covalent binding of the two TCR chains. This cysteine is absent in the duplicated or triplicated exon II of the human Cγ2 gene, but the corresponding γ chain can still form functional TCR by pairing noncovalently with the TCRδ chain (Lefranc and Rabbitts 1989). The transmembrane region of each TCR subunit (21–22 amino acids long) is encoded by a third exon. Although strongly hydrophobic, this region comprises one or two positively charged residues that establish electrostatic interactions with acidic residues located in the transmembrane region of several subunits of the CD3 signal transduction complex. Mutation of these residues abrogates CD3/TCR assembly (Hall et al. 1991). The short TCR chain intracytoplasmic region (4–12 amino acids) is

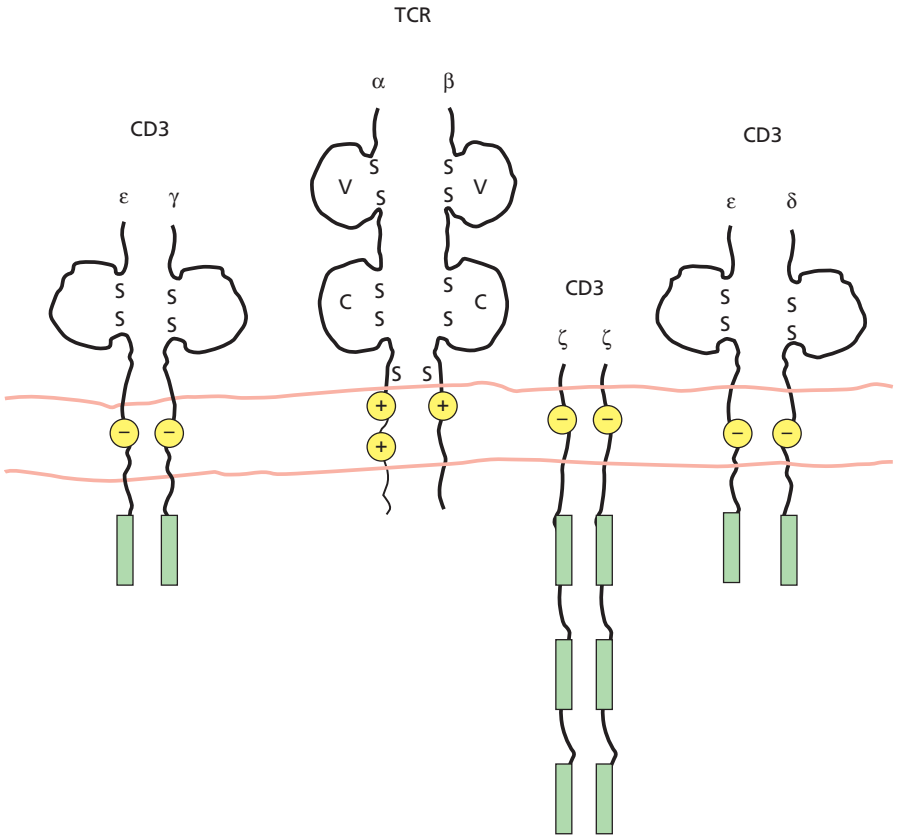

Figure 7 *Overall structure of the T-cell receptor (TCR)/CD3 complex. See the text for details. − and + symbols correspond to acidic and basic residues located within the transmembrane region of TCR and CD3 chains. ITAMs located on the intracellular portion of CD3 subunits are symbolized by rectangles. S-S, disulfide bridges.*

encoded by either exon III (for Cβ genes) or a fourth exon (for Cα genes) (Figure 8).

THE CD3 TRANSDUCTION COMPLEX

None of the TCR subunits possesses a cytoplasmic tail long enough to permit signal transduction after antigen recognition. This function is mediated by a multimeric complex called CD3, which is closely associated with the αβ and γδ TCR and required for TCR surface expression (Sussman et al. 1988; Hall et al. 1991) (see Figure 7). In this way, the TCR complex appears very similar to the BCR complex, which consists of an antigen recognition unit (the membrane-bound immunoglobulin) associated with a transduction complex composed of Igα and Igβ subunits (see Antibodies and B lymphocytes). Five distinct CD3 subunits, called γ, δ, ϵ, ζ, and ν, have been biochemically identified within the CD3 complex (Borst et al. 1983). In most instances, the CD3 complex is composed of four distinct subunits (γ, δ, ϵ, and ζ) that are organized in three dimeric transduction modules: γϵ, δϵ, and ζζ (Alarcon et al. 1991). CD3γ, -δ, and -ϵ are encoded by highly homologous genes located within a 50-kb region on chromosome 11 in human and 9 in the mouse (Letourneur et al. 1989). The CD3ζ gene is located on chromosome 1 and can undergo an alternate splicing in the mouse, which leads to generation of either a CD3ζ or a CD3ν protein (Jin et al. 1990). Although the CD3 γ, δ, and ϵ chains possess a single Ig-like ectodomain of 80 amino acids, the CD3-ζ and ν chains have a very short (nine amino acids) extracellular region. All CD3 subunits contain a negatively charged acidic residue (Asp) in their transmembrane region, which ensures proper assembly of the CD3/TCR complex (see above). The intracytoplasmic tail of all CD3 subunits contain one (for CD3γ, -δ, or -ϵ) to three (for CD3ζ) consensus motifs called immuno-tyrosine-based activation motif (ITAM) (Reth 1989). These motifs, also found in a variety of other immune receptors (such as Igα/β and some Fc receptors), play a key role in signal transduction by interacting, once phosphorylated, with specific tyrosine kinases required for the initiation of the signaling cascade (like ZAP-70 in T cells) (see also The B cell antigen receptor). The composition and stoichiometry of CD3 complexes may differ from one T cell to another. In the mouse, about 5–10 percent of $CD3^+$ lymphocytes express ζν heterodimers instead of ζζ homodimers (Baniyash et al. 1988). Although ν is not found on human T cells, some $CD3^+$ T cells in both species may utilize the FcϵRIγ subunit instead of the ζ chain (Koyasu et al. 1992). The qualitative/quantitative differences of the signals initiated by CD3 complexes containing ζζ, ζν, or FcϵRIγ dimers are still unclear. Finally the composition of CD3 complexes associated with αβ and γδ TCR show differences: unlike αβ TCR complexes, γδ TCR complexes lack CD3δ and rapidly recruit FcϵRIγ on T-cell activation (Hayes and Love 2002).

THE CD4 AND CD8 CO-RECEPTORS

Interactions between the αβ TCR and pMHC complexes are classically strengthened by the CD4 or CD8 co-receptors, which bind to the conserved part of MHC class II and class I molecules respectively. As detailed in CD4+ T lymphocytes and 22, The role of CD8 T cells in the control of infectious disease and malignancies, these co-receptors also play a key role in the initiation of signal transduction by recruiting $p56^{lck}$, which then mediates early phosphorylation of ITAM on the CD3 subunits. As the CD4 and CD8 co-receptors modulate the avidity of TCR/pMHC interactions, they play a critical function during the intrathymic selection of the TCR repertoire and the terminal maturation of CD4/CD8 double-positive thymocytes into CD4 or CD8 single-positive T cells (Ellmeier et al. 1999).

TCR crystallographic analyses

αβ TCRS

Although Ig can interact with high affinity with a wide variety of native antigen, αβ TCRs must recognize subtle differences between MHC molecules loaded with distinct peptidic antigen. This task is facilitated by the concentration of the TCR structural diversity at the center of the TCR/pMHC interface. As with Ig, diversity of rearranged TCR genes is not evenly distributed within the variable region but is instead clustered in so-called hypervariable (HV) regions. There are two HV regions within the V gene segment (HV1, HV2) and a third one corresponding to the V(D)J junction. These three regions code, respectively, for the complementarity determining regions (CDR)-1, -2 and -3 that form the antigen-binding site (see below). A fourth hypervariable region (HV) 4 has been identified in the V region, which forms an additional loop involved in superantigen binding (see 'Structural basis of T-cell antigen recognition' below and see Superantigens). Consistent with earlier predictions, the overall TCR structure is very similar to that of an Ig Fab fragment (Figure 9) (for a recent review, see Garcia et al. 1999).

The C and V domains of both TCR chains adopt a classic 'Ig fold' composed of a sandwich of two β sheets with five inner and four outer β strands for the V domains, and four inner and three outer strands for the carboxyl domains (see also Antibodies and B lymphocytes, and The B cell antigen receptor). As for Ig, the CDR loops protrude on top of the V domains to form the antigen-binding site. TCRs also show several distinctive structural features, listed below. The Cβ domain carries a large protruding loop

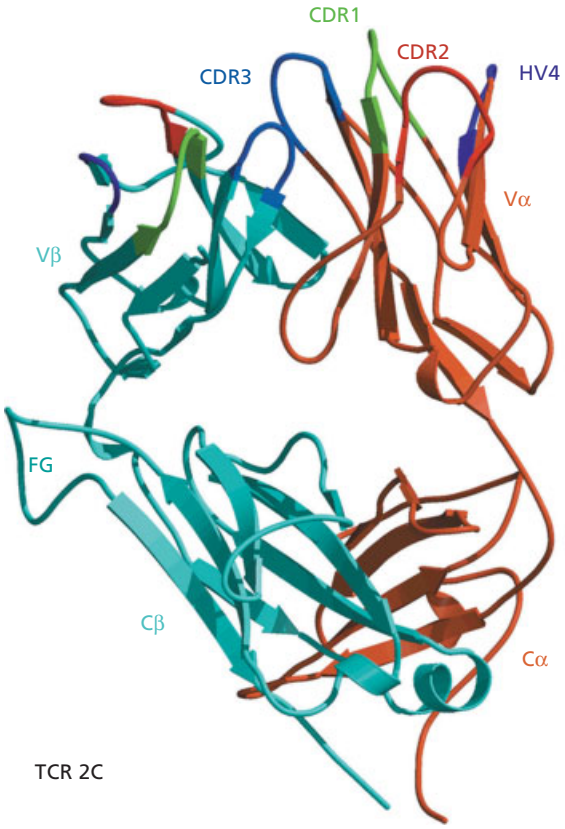

Figure 9 *Three-dimensional structure of an αβ T-cell receptor (TCR). See the text for details. Structure of a murine TCR. (Kindly provided by J.B. Reiser and D. Housset, Grenoble, France.)*

between the F and G strands, the significance of which remains unclear. It may facilitate interactions with either some CD3 subunits (Ghendler et al. 1996) or co-receptors. The elbow angle between Vβ and Cβ is fairly constant (between 140° and 150°) contrasting with the much higher flexibility of Ig, with elbow angles ranging from 120° to 225°. Furthermore, the Cα domain shows some structural differences with canonical Ig folds and in particular lacks a C′ and C″ strand. This unusual feature is anticipated from the primary Cα sequence because only 50 amino acids separate the two cysteines, forming the intradomain disulfide bridge in the Cα domain, compared with around 65 amino acids for the Cβ or Ig constant domains. The antigen-binding site of αβ TCR is made of six hypervariable (CDR) loops, three from each Vα and Vβ domain. CDR1 and CDR2 are located in the periphery whereas the two CDR3 are located centrally. While the CDR1 and CDR2 from the Vα and Vβ domains seem to adopt a limited set of canonical conformations, the CDR3α and CDR3β show substantially different conformations and undergo extensive conformational changes upon pMHC bin ing (see below). In this regard, the lack of canonical CDR3 structures is fully consistent with the extensive sequence diversity of the VJα and VDJβ joints (see 'Genomic organization and source of TCR diversity' above).

γδ TCRS

The sole γδ TCR structure resolved so far (Allison et al. 2001) has a highly distinctive overall shape, when compared with αβ TCR or Fab fragments. This unusual shape is produced by a small elbow angle and a small VγCγ interdomain angle, which are both the smallest ever seen within Fabs and TCR structures. Both the Cδ and Cγ domains adopt a canonical Ig fold but the Cγ domain, which is more homologous to Cβ than Cα, does not have the long FG loop found in the Cβ domain. The antigen-binding surface of the γδ TCR appears much rougher than that of αβ TCR. This peculiar feature seems to result mainly from the unusual positioning of the CDR2δ (also seen in crystals of another Vδ domain (Li et al. 1998)), and to large protrusions formed by the CDR3γ and CDR3δ loops. Together with parts of the CDR1 and CDR2 loops, the CDR3 loops form a deep cleft that may constitute the antigen-binding site. Consistent with an Ig-like mode of antigen recognition by γδ TCRs (Chien et al. 1996; see Unconventional T cells), the jagged antigen-binding surface of the γδ TCR resembles that of an antibody specific to small proteins. However, general predictions about the topology of γδ TCR/antigen interactions, based on analysis of a single unbound γδ TCR, should be taken with caution, particularly in light of the dramatic conformational modifications occurring on the CDR3 loops of several αβ TCR on binding to their pMHC complexes (Reiser et al. 2002).

STRUCTURAL BASIS OF T-CELL ANTIGEN RECOGNITION

Crystallographic analysis of antibody TCR bound to pMHC complexes

As the vast majority of amino acid variations lie in the V(D)J junctional regions, which are equivalent to the centrally located CDR3 within the Ig antigen-binding site, it has been proposed that the CDR3β loops from the Vα and Vβ domains line up above the antigenic peptide, whereas the less diverse CDR1 and CDR2 interact with the MHC molecule (Davis and Bjorkman 1988). As suggested by TCR and MHC mutagenesis studies (Jorgensen et al. 1992; Sant'Angelo et al. 1996) and more recently confirmed by crystallographic analyses of several TCR/pMHC structures (Garcia et al. 1999), some but not all of these assumptions proved to be correct.

Determination of the crystal structure of TCR/pMHC complexes has represented a particularly challenging task, not only because of the difficulties in producing and purifying large quantities of TCR and pMHC and generating stable trimolecular complexes, but also because of the crystallographic problems associated with analysis of such large macromolecular complexes. This explains why only a handful of high-resolution TCR/

pMHC complex structures have been reported so far. Despite this, several general principles for recognition of pMHC by TCR can already be drawn from the few structures determined to date (Figure 10).

OVERALL TOPOLOGY

The TCR adopts a diagonal orientation over the pMHC complex in all the TCR/pMHC class I and class II structures resolved so far (Garcia et al. 1996, 1999) (Figure 10a, b). This particular topology probably maximizes the cooptation between the MHC and TCR surfaces, because it allows the relatively flat TCR binding surface to lie between the two opposite high points of the MHC α helices (Garboczi et al. 1996). In all instances, the Vα domain is located over the amino-terminal half of the peptide and the Vβ domain over the carboxy-terminal half. Here again this orientation is likely to be conserved, in order to ensure proper positioning of the CD4 and CD8 co-receptors within the TCR/pMHC complex.

CDR FOOTPRINTS ON THE PMHC

Both CDR3 loops lie centrally and establish contacts almost exclusively with the antigenic peptide (Figure 10a, b). The CDR1α and β interact with both MHC and peptide residues whereas the CDR2 contacts almost exclusively the MHC α helices. Early crystallographic studies suggested a dominant contribution of the Vα (over the Vβ) CDRs to TCR/pMHC interaction, and frequent involvement of conserved residues at the tip of CDR1α and CDR2α loops in TCR/MHC contacts at conserved MHC areas, thus supporting a key role for

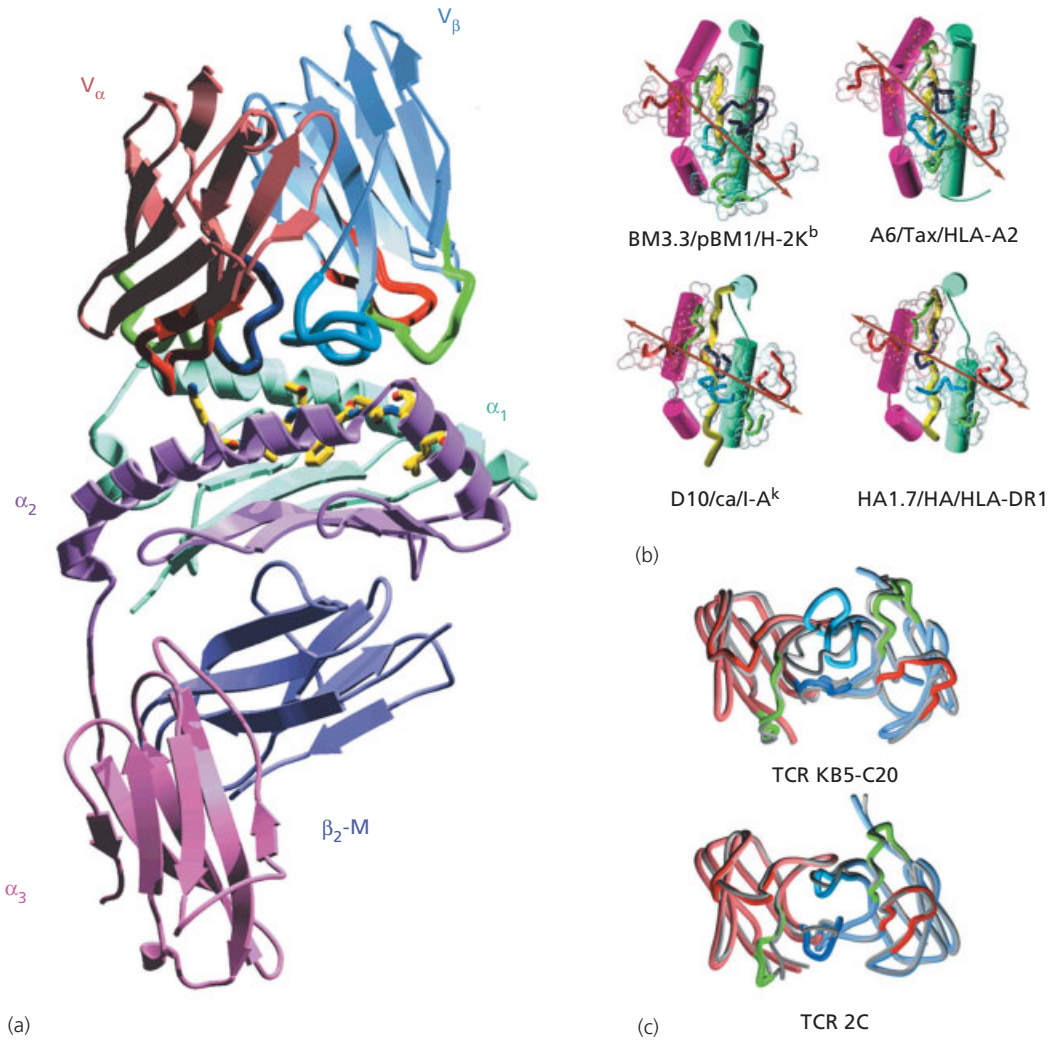

Figure 10 *Structure and overall topology of the T-cell receptor (TCR)/pMHC complex. the Vα domain in driving the TCR orientation over the pMHC complex (Garcia et al. 1998). This hypothesis has been more recently challenged by the balanced contribution of Vα and Vβ domains to pMHC interaction observed in additional structures, and the significant tilting of the TCR over the 'MHC saddle' from one complex to another (Reiser et al. 2000, 2002). Importantly these studies have failed to identify a truly conserved TCR footprint on the MHC shared by all TCR/pMHC class I complexes. Thus, there is so far no straightforward structural explanation for the inherent MHC reactivity of the TCR documented by biological studies (Zerrahn et al. 1997).

MHC VS PEPTIDE INTERFACE

Clearly the dominance of TCR contacts with the MHC helices should provide enough binding energy between the TCR and MHC heavy chain to allow proper TCR docking on the complex and subsequent scanning of its peptide content (see below). Furthermore comparison of bound versus unbound TCR indicates large conformational changes occurring mainly on the CDR3 loops, which may compensate for the relatively poor shape complementarity between the peptide and the TCR loops (Garcia et al. 1998; Reiser et al. 2002) (Figure 10c). Hence, this suggests an important plasticity of the T-cell recognition process, and provides a likely molecular explanation for the ability of a given T cell to recognize, in a degenerate fashion, large sets of peptides during its intrathymic positive selection or its peripheral activation.

ALLOREACTIVITY

A large fraction of T cells (up to several percent) cross-reacts to allogeneic MHC molecules. The molecular basis of this phenomenon, called alloreactivity, has been deciphered during the last decade and turns out to cover distinct types of interactions. In most cases, recognition of allogeneic cells appears mildly affected by the peptidic content of the recognized MHC molecules, suggesting highly degenerate low-affinity interactions between TCR and a large fraction of allogeneic pMHC complexes. Some alloreactive TCRs may also recognize, with much higher affinity and in a more peptide-dependent fashion, allogeneic MHC alleles related to self-MHC (Obst et al. 2000). Comparison of TCR bound to a positively selecting pMHC complex or an allogeneic pMHC suggests that some interactions with MHC in the former case can be 'mimicked' by interactions occurring with the peptide in the latter case (Garcia et al. 1998; Reiser et al. 2000). As a result of the heterogeneity of alloreactive responses documented by biological studies (see above), other molecular explanations (such as weak cooptation between the TCR and pMHC surfaces associated with increased peptide degeneracy) seem highly likely although they need confirmation through resolution of additional structures.

Structure of αβ TCR/superantigen complexes

Antigens are not always recognized in a form of MHC-bound peptide because some of them may directly bind to the TCR and MHC class II molecules in a native form. This particular class of TCR ligands, which is produced by a variety of microbial and viral pathogens, are called superantigens (SAg) because they can activate a substantial fraction of naive T cells. As briefly mentioned below and detailed in Superantigens, the TCR-binding modes of antigen and SAg are drastically different because MHC class II-bound SAgs can engage all TCRs sharing a particular Vβ (or Vγ) region, irrespective of their Vα (or Vδ) regions and their VDJβ (or VJγ) junctional sequences. This explains why a given SAg can activate up to several percent of the total T-cell repertoire in naïve individuals. Crystallographic analysis of TCR/SAg and SAg/MHC class II complexes has clearly confirmed the peculiar topology of these interactions (Li et al. 1999). Although different SAgs bind to class II MHC in very different ways, their mode of interaction with the TCR appears quite conserved: in most instances, SAgs establish contacts with the HV4 as well as the CDR1 and CDR2 loops of the Vβ chain. This is in stark contrast with TCR/pMHC complexes, for which pMHC contacts involve residues located on all six CDRs but not HV4 (see above). Importantly the orientation of the TCR over the MHC molecule within the TCR/SAg/MHC complex is very different from that in TCR/pMHC complexes, and does not permit proper interaction with the bound peptide, which is consistent with previous observations demonstrating TCR/SAg/MHC interactions irrespective of the bound peptide (Li et al. 1999).

A DYNAMIC VIEW OF THE T-CELL ANTIGEN RECOGNITION PROCESS

Analysis of TCR/pMHC interactions

AGONISM VS ANTAGONISM

TCR engagement by pMHC complexes does not always lead to full T-cell activation. In particular alteration of the antigenic peptide sequence may affect T-cell functions in very different ways. Although some peptide mutants referred to as full agonists retain the ability to activate all T-cell effector functions, others referred to as weak or partial agonists may induce decreased T-cell responses or some but not all effector functions (Evavold and Allen 1991). In extreme cases, T-cell response to agonist peptides may be inhibited after

exposure to some altered peptide ligands referred to as antagonists (for a review, see Sloan-Lancaster and Allen 1996). The physiological relevance of these nonproductive or suboptimal TCR/pMHC interactions is still unclear. They may affect T-cell responses against infections and/or may contribute to the selection of the T-cell repertoire as well as peripheral T-cell homeostasis. From a mechanistic point of view, antagonist peptides do not seem to compete with agonist peptides for binding to MHC molecules. Instead antagonists may engage either sterile or abortive TCR interactions (Sloan-Lancaster et al. 1994; Madrenas et al. 1995), thus decreasing the number of productive TCR/agonist interactions and/or triggering an inhibitory signal that dominates the activating signal induced by the agonist. Some biophysical studies, detailed below, have brought important insights into this phenomenon although we do not have yet a clear picture of what precisely is going on.

αβ TCR/PMHC-BINDING STUDIES

Analyses of TCR/pMHC interactions have lagged far behind those of antigen–antibody interactions because of two major technical obstacles. First, the membrane-bound nature of the TCR and MHC molecules, and the relative instability of TCR heterodimers when expressed under soluble forms, have greatly hampered their large-scale production and purification. A second problem lies in the affinity of pMHC/TCR interactions, which have turned out to be in the lower micromolar range, and measurable only using recently available surface plasmon resonance technologies. Indeed the affinity of TCR/pMHC interactions (K_d values in the order of 10^{-4}–10^{-7}) is on average lower than that of antibody–antigen interactions (K_d values of 10^{-6}–10^{-10}). Although the on-rates of TCR/pMHC interactions are quite heterogeneous (from 10^3 to 2.10^5 mol/l per s), their off-rates are very fast and remain in a relatively narrow range (from 0.2 to 0.005/s at 25°C). These fast off-rates have led to the proposal that T-cell activation by a small number of pMHC complexes would be made possible by the transient engagement of many different TCRs within a short time lag (Valitutti et al. 1995). However, the correlation between the strength of the T-cell response and the off-rates of TCR/pMHC interactions is still being debated. In their 'serial TCR engagement' model, Lanzavecchia and colleagues propose that lower TCR/pMHC off-rates should lead to reduced T-cell activation as a result of decreased numbers of serially engaged TCR within a given time frame (Viola and Lanzavecchia 1996). However, this hypothesis is difficult to reconcile with the inverse correlation observed by other groups between TCR/pMHC dissociation rates and T-cell responsiveness (for a recent review, see Davis et al. 1998). Indeed the TCR-binding affinity for strong pMHC agonists appears to be generally much higher than for antagonists. Furthermore, binding of TCRs to weak agonists and antagonists may show very similar affinities but different dissociation rates, which can be up to 10-fold higher in the latter than in the former case (Matsui et al. 1994; Lyons et al. 1996). Molecular explanations for this phenomenon are still pending but recent studies suggest that antagonist peptides prevent efficient TCR clustering and subsequent maturation of the immunological synapse (see above).

Although crystallographic studies allow identification of all the residues involved in a given interaction, many of these interactions can be neutral (i.e. mutation of the corresponding residues may have no impact on the binding affinity). Systematic mutagenesis analyses performed on either the TCR or the pMHC complex have allowed mapping of energetic 'hotspots' involving only a small fraction of interacting residues identified by X-ray analyses (Baker et al. 2001). Interestingly, the nature of TCR/MHC and TCR/peptide interactions may fundamentally differ, as suggested by another recent mutagenesis study (Wu et al. 2002). Mutations introduced within the antigenic peptide have a dramatic effect on the stability of the TCR/pMHC complex. This decreased affinity, when measurable, seems mainly accounted for by a marked increase of the dissociation constant, with only a minor effect on the association constant. By contrast, mutations on the MHC molecule have significantly less impact on the stability of pMHC/TCR interaction and, in most instances, this effect results from a decrease of the association constant. These results suggest a two-step mechanism for T-cell antigenic recognition. In a first step, interactions between TCR residues on the CDR1 and CDR2 loops and MHC residues would permit docking of the TCR on the MHC molecule, and scanning of its peptide content. In a second step pMHC/TCR binding would be stabilized on forming a complex via an induced conformational fit of the CDR3 loops, already documented in several crystallographic studies (Garcia et al. 1998; Reiser et al. 2002). This two-step process is also consistent with the entropic changes of TCR/pMHC interactions reported in several thermodynamic analyses (Willcox et al. 1999; Boniface et al. 1999).

γδ TCR/ANTIGEN-BINDING STUDIES

Unlike αβ T cells, γδ T cells do not generally recognize peptide antigens bound to classic MHC class I and class II molecules. As detailed in Lymphocyte mediated cytotoxicity, γδ TCRs seem to interact with native antigen in an Ig-like fashion. This assumption is consistent with the extensive structural heterogeneity of the TCRγδ ligands identified so far, which include native MHC or MHC-like proteins, viral glycoproteins, Ig, heat shock protein (HSP), and small phosphorylated esters commonly produced by microorganisms (Chien et al. 1996). The sole biophysical binding study performed to

date with a γδ TCR directed against an 'empty' MHC class I-like molecule has revealed several unusual features. The affinity of this interaction appears much higher than that of αβ TCR/pMHC interactions, resulting mainly from a very low dissociation rate (Crowley et al. 2000). As, in this particular case, the MHC class I-like molecules recognized by the γδ TCR are expressed at high densities on target cells, γδ T-cell activation is probably induced after stable engagement of a large number of TCRs by their ligands. These high avidity/high affinity interactions might be common within nonconventional T cells, as suggested by another recent binding study performed with an αβ TCR specific for CD1d/glycolipid complexes (Sidobre et al. 2002).

The immunological synapse

Although the half-lives of TCR interactions are of the order of seconds, the duration of signaling required for T-cell activation is of the order of hours, thus suggesting specific mechanisms permitting sustained TCR interactions with their specific pMHC complex. This is achieved through the formation of supramolecular activation clusters (SMAC), which consist in a highly organized clustering of TCR, co-receptors, co-stimulatory, and adhesion receptors as well as signaling molecules within lipid rafts enriched for glycolipids and glycosphingolipids (Monks et al. 1998; Grakoui et al. 1999) (Figure 11).
These SMACs of immunological receptors, which form within minutes after contact between the T cell and the antigen-presenting cell (APC), are classically referred to as the immunological synapse. Although a detailed description of the formation and function of the immunological synapse is clearly beyond the scope of the present chapter, several general features of the immunological synapse are outlined here.

T-cell activation and immunological synapse formation can be grossly split into four distinct temporal stages corresponding to: (1) the initial T-cell polarization events taking place shortly after APC encounter; (2) the segregation of adhesion molecules within early supramolecular clusters leading to enhanced T-cell adhesion to APC; (3) early TCR-signaling leading to formation of the immature immunological synapse; and finally (4) immunological synapse maturation associated with sustained TCR signaling (Bromley et al. 2001).

T-CELL POLARIZATION

Initial adhesion of the T cell to the APC is accompanied by rapid membrane reorganization and T-cell polarization, presumably in response to chemokines (Sanchez-Madrid and del Pozo 1999). Subsequent signaling through heterotrimeric G protein then triggers actin polymerization and integrin activation. The engaged integrins can in turn promote the formation of membrane protrusions tipped by TCR-enriched membranes, which are probably involved in the initial scanning of pMHC complexes and set the initial stages of immunological synapse formation (Dustin and Cooper 2000).

T-CELL ADHESION TO APCS

Effective adhesion between the T cell and the APC requires rapid segregation of adhesion and recognition receptors within these early supramolecular arrangements. Although surface molecules with large extracellular domains (such as CD43 and CD45) are excluded, smaller adhesion receptors such as CD2 and LFA1 are clustered in the center of the structure and form tight interactions with their counterreceptors (CD58 and intercellular adhesion molecule 1 (ICAM-1), respectively) (Sperling et al. 1998; Grakoui et al. 1999; Leupin et al. 2000).

IMMUNOLOGICAL SYNAPSE FORMATION AND MATURATION

In its initial stage, the immunological synapse is made up of an adhesion molecule cluster surrounded by a ring of engaged TCRs. Along immunological synapse maturation, the structure is inverted: the engaged TCR/pMHC complexes progressively move toward the center of the SMAC (cSMAC) whereas the adhesion molecules move to its periphery (pSMAC) (Grakoui et al. 1999). Although it seems clear that the earliest TCR signaling events induce the cytoskeletal changes required for immunological synapse maturation, the parameters (quantitative or qualitative) controlling sustained signaling within the mature immunological synapse are still poorly defined. Stable formation of the immunological synapse seems to be associated with the recruitment of specific kinases required for full T-cell activation (such as protein kinase C) (Monks et al. 1998). Furthermore CD28, which segregates within the cSMAC in the mature immunological synapse, probably plays an important role in the potentiation of TCR signaling because its co-engagement with the TCR has been shown to sustain TCR-induced tyrosine phosphorylations (Viola et al. 1999). As already mentioned, nonproductive TCR/pMHC interactions (e.g. with high off-rates as observed with some antagonist peptides) may dramatically reduce the density of TCR/pMHC complexes within the mature immunological synapse and thus affect sustained signaling.

CONCLUDING REMARKS

Recent studies are shedding light on several common principles that underlie T-cell antigen recognition and its translation into particular biological outcomes. Recognition of pMHC by TCRs turns out to be a complex multistep process, which involves induction of conformational changes of TCRs on binding and rapid recruitment of adhesion and co-stimulatory receptors within highly

organized membrane receptor clusters. Naturally, there are still several challenging issues that should be addressed by future work. Structural explanations for the inherent MHC reactivity of TCR are still lacking and will certainly need resolution of additional TCR/pMHC structures. Biophysical and thermodynamic

analyses of TCR/pMHC interactions should help clarify the mechanisms underlying the biological effects of altered peptide ligands. Finally a precise understanding of how the T cell integrates the activating and inhibitory signals that are concomitantly generated during encounter of APCs will be another major challenge, which will probably require the combined use of sophisticated molecular, biochemical, and morphological approaches.

Cytotoxic lymphocytes and their killing machinery, the cytolytic granule, are a critical component of the immune response. They are required for the removal of intracellular pathogens and for immune surveillance against tumors. This function necessitates the use of a fail-safe system, embodied by perforin and granzymes that act cooperatively in the clearance of even non-cooperative cells, such as virus-infected and transformed tumor cells. Although cytotoxicity and perforin have a well-understood functional role in the effector pathway of cyototoxic lymphocyte (CTL) and natural killer (NK) cells, it is only now being appreciated that perforin also has important functions in the induction of the adaptive CTL response. Finally, perforin and the granule exocytosis pathway of cytotoxicity are also critical for maintaining homeostasis of the CD8 T-cell compartment and downregulation of CTL memory responses. Cytotoxicity and perforin thus play a complex role in induction of CTL, in their effector function, and in the homeostasis of the CTL response. We are only beginning to understand the implications of these observations. Controlling and manipulating cytotoxicity are the holy grail of tumor immunology and antiviral therapy; there is every hope that further understanding of cytotoxicity will bring this goal within our grasp.

CYTOTOXIC LYMPHOCYTES

Two types of lymphocytes exist with regard to cytotoxicity: constitutively cytotoxic cells and inducibly cytotoxic lymphocytes. NK, NK-T, and γ,δ-T cells have constitutive cytotoxic activity and are able to kill targets without the need for induction. In contrast, naïve CD4 and CD8 T cells require activation and clonal expansion, accompanied by differentiation into CTLs. This process is driven by antigen stimulation with the help of several co-stimulatory molecules, and is accompanied by the acquisition of cytoplasmic granules containing the molecules responsible for target cell lysis, principally perforin and granzymes. Memory CTLs are similar to naïve T cells with regard to cytotoxic activity, except that their reacquisition of cytotoxicity is much more rapid than that of naïve cells.

The ability to kill a given target cell is determined by the specificity of cell surface receptors, whereas the killing process itself is unspecific. Once a killer cell has recognized a cell as a target, the killing machinery (the cytolytic granules) is engaged and kills the target indiscriminately and independently of target cooperation. The decision to kill is made by recognition rather than by downstream events. This decision tree is quite unlike the decision of a target to commit apoptosis, which

depends on apoptotic receptor engagement *and* downstream signaling events. Apoptotic receptor engagement can indeed result in cell proliferation via NFκB activation. Targets recognized by CTLs or NK cells are not asked for compliance in dying; they are killed by multiple lytic, apoptotic, and nonapoptotic pathways without recourse to protection.

Recognition of targets by CTLs is achieved by the T-cell receptor binding to major histocompatibility complex (MHC) peptide complexes, triggering tight binding to the target, and killing by granule exocytosis. NK cells, NK-T cells, and γ,δ-T cells recognize a variety of surface molecules, not all of which have been defined. Killing by NK cells is, however, primarily determined by the engagement, or lack thereof, of dominant NK cell inhibitory receptors binding to the MHC class I molecules. If the target expresses normal levels of MHC the dominant killer cell inhibitory receptors will prevent activation of the cytolytic program by dephosporylation of intracellular substrates, even when positively signaling receptors are engaged. CTLs thus kill by MHC recognition whereas NK cells kill only in the absence of MHC molecules. This complementarity of recognition by CTLs and NK cells is an important mechanism to prevent the evasion of virally infected cells from the immune response.

Viruses must express viral genes and proteins during replication and some of the viral peptides will be presented by MHC and detected by CTLs. Virus-mediated downregulation of MHC molecules effectively prevents detection by T cells; however, absence of MHC allows NK cell killing. Viruses are therefore challenged to evolve mechanisms by which both NK cell and CTL evasion is achieved. Two mechanisms are known: cytomegalovirus (CMV) downregulates MHC expression of infected cells, thereby avoiding T-cell detection; in order to avoid killing by NK cells, CMV encodes a viral class I MHC molecule that is expressed on the infected cell and recognized by the inhibitory receptors of the NK cell, thereby inhibiting the killing activity. HIV nef downregulates HLA-A and -B molecules but not HLA-C molecules. As T-cell responses are primarily restricted by HLA-A and -B, CTLs will not be able to recognize HIV-infected cells; as HLA-C engages a large pool of NK cells through the inhibitory receptors, HIV-infected cells are also protected from NK cell attack.

It is evident from these examples that the primary function of cytotoxic lymphocytes is to clear our body of virus-infected cells and other intracellular parasites; this biological task is under continued evolutionary pressure by evolving pathogens. As the genesis of tumors is accompanied by multiple mutations and generation of neoantigens, oncogenic transformation may also be considered as parasitization of cells. As we shall see this process is under surveillance by cytotoxic cells protecting us from carcinogens and spontaneous tumor formation. Autoimmunity is the result of dysregulated immune responses and is frequently accompanied by infiltration of tissues with cytotoxic cells. Cytotoxic cells are generated after allogeneic bone marrow transplantation and contribute to graft-versus-host disease. In allogeneic organ transplantation invasion of cytotoxic cells is one of the hallmarks of organ rejection.

CTLS AND NK CELL MORPHOLOGY AND FUNCTION

Cytotoxicity is a specialized secretory process and CTLs and NK cells are secretory cells (Dennert and Podack 1983; Podack and Dennert 1983; Henkart et al. 1984; Podack and Konigsberg 1984; Henkart 1985; Podack 1985, 1989; Podack and Kupfer 1991; Podack et al. 1991; Kagi et al. 1994, 1996; Berke 1995; Liu et al. 1995; Podack, 1995a, b; Griffiths 1997; Zhang et al. 2001; Blott and Griffiths 2002; Djeu et al. 2002. Secretion of stored granules, also known as granule exocytosis, is the hallmark of the cytolytic process. Secretory cells come in three flavors (Figure 1):

1. Constitutively secreting cells: constitutive secretion describes a secretory process occurring continuously without external trigger. Antibody secretion by B cells is the classic example. Membrane-bound vesicles containing the cargo bud of the trans-Golgi network fuse with the plasma membrane, releasing their cargo or inserting membrane proteins into the plasma membrane.
2. Regulated secretion of storage granules is dependent on triggers and Ca^{2+} signals for release of intracellularly stored products. Secretory vesicles budding of the trans-Golgi network fuse with the secretory granule, where the cargo materials are concentrated with the aid of proteoglycans. This type of secretion is typical for endocrine and exocrine glands. In these cells lysosomes and granules are clearly distinct and distinguishable organelles receiving input from the Golgi apparatus by separate vesicular pathways.
3. Regulated secretion of secretory lysosomes (granulosomes) is the process used by cytolytic lymphocytes. Although all cells have lysosomes, only specialized cells have secretory lysosomes. Secretion is triggered by external stimuli and Ca^{2+} signals. Secretory lysosomes are specialized organelles receiving input from the Golgi body through the mannose-6-phosphate receptor pathway used by lysosomes and from the plasma membrane through endocytic vesicles and endosomes. Only lymphocytes, granulocytes, mast cells, platelets, melanocytes, and some renal epithelial cells are equipped with secretory lysosomes (Dennert and Podack 1983; Griffiths 1997; Pham and Ley 1997; Simon et al. 1997).

CTLs and NK cells are indistinguishable by electron microscopic morphology (Figure 2) (Henkart et al.

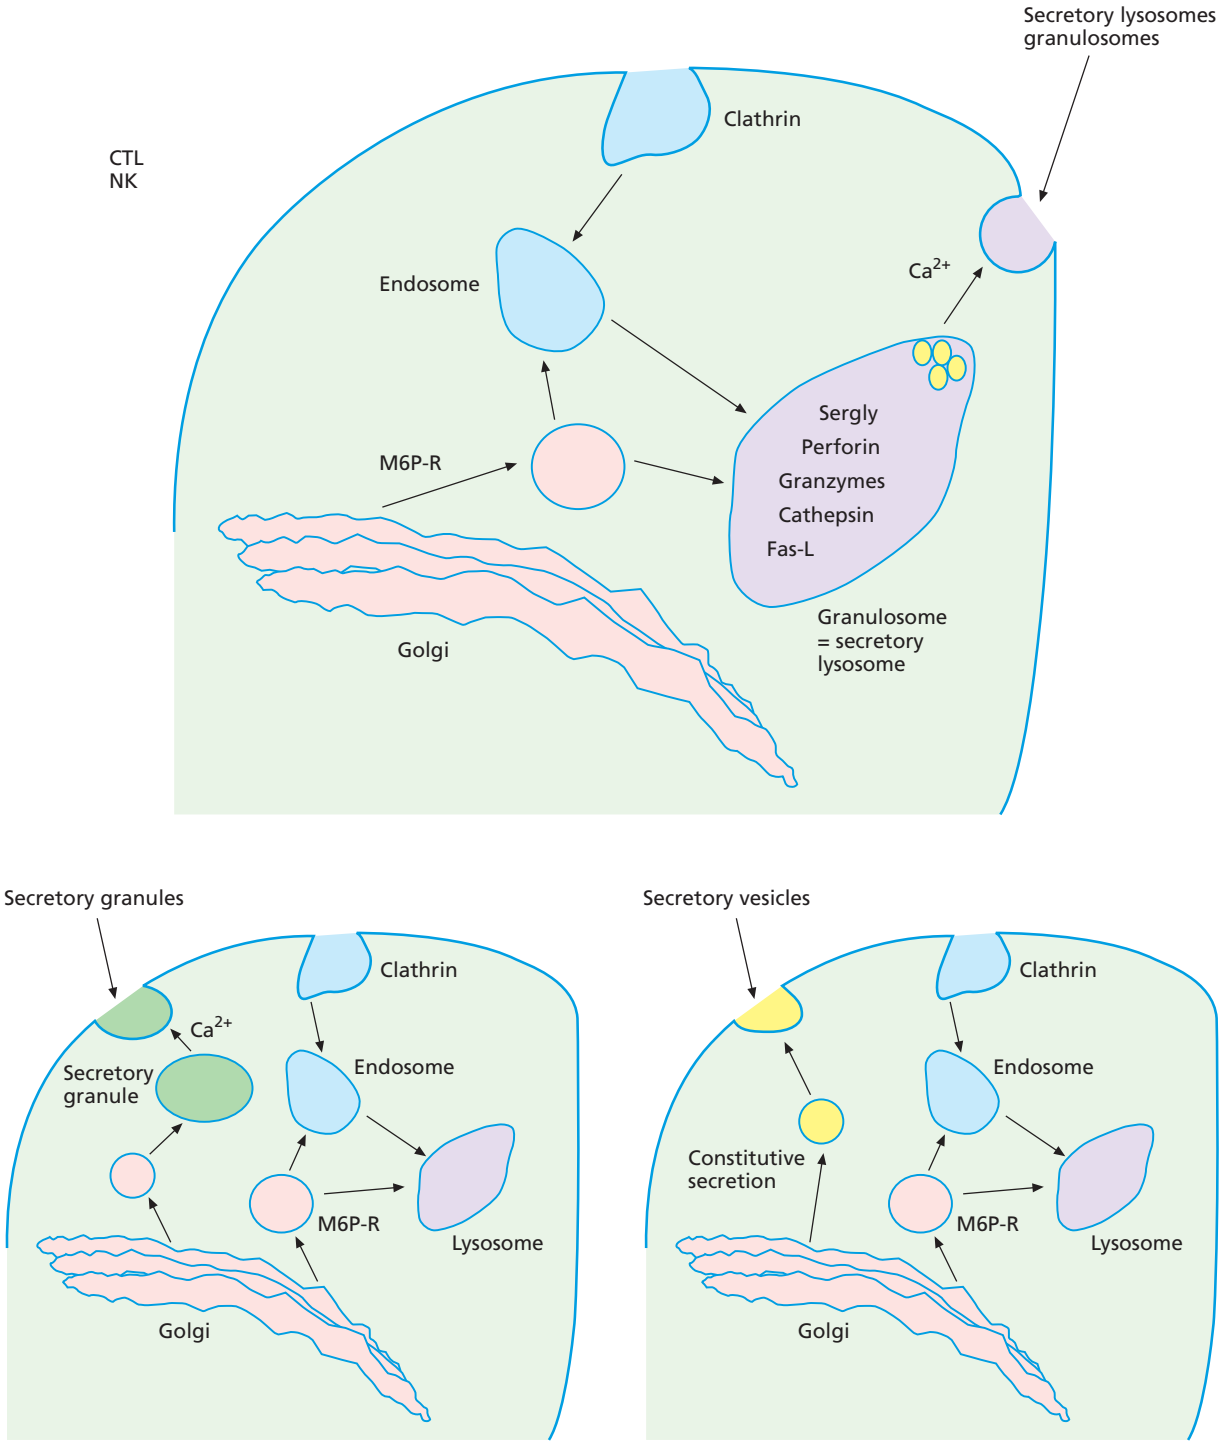

Figure 1 *Three types of secretory cells. Top: secretory lysosomes (granulosomes), this type of regulated secretion is used by cytotoxic lymphocytes (CTLs) and natural killer (NK) cells. Lower left: regulated secretion of storage granules, used by exocrine and endocrine glands. Lower right: constitutive secretion used, for example, by antibody-secreting B cells.*

1984; Podack 1995b; Uellner et al. 1997). The cells are characterized by a reniform or lobed nucleus, a well-developed active endoplasmic reticulum, a pronounced Golgi apparatus, and large granules (secretory lysosomes, granulosomes). The granulosomes are characterized by a dense core and areas containing vesicular, apparently membrane material. The significance of the vesicular material is not known; however, it may indicate storage of membrane-bound mediators such as the Fas ligand (Fas-L).

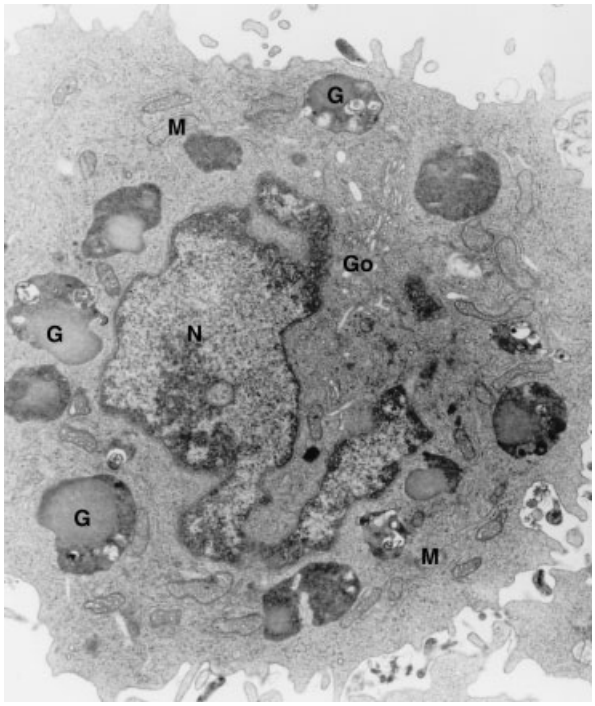

Figure 2 *Morphology of cytotoxic lymphocyte. G, granulosome; Go, Golgi body; M, mitochondria; N, nucleus.*

KILLING

On target recognition and T-cell receptor (TCR) triggering the cytolytic synapse is formed. The synapse is bordered by a tight adhesion ring composed of integrins (lymphocyte-mediated cytotoxicity 1 (LFA-1)) on the CTL side and of corresponding ligands (intercellular adhesion molecule 1 (ICAM)) on the target. The integrins are anchored via talin to the cytoskeleton of the CTLs. From inside the adhesion ring signals emanate via TCR-associated kinases and activate Erk-kinase, which in combination with Ca^{2+} fluxes results in a complex reorientation of the killer cells. The Golgi body and the microtubule-organizing center (MTOC) are brought to the area of contact between killer and target, and vectorial migration of granules toward the synapse is initiated (Figure 3). Only individual or few granules are secreted before the synapse is broken, allowing the CTLs to attack many targets in succession without having to replenish the granule supply. The process of synapse formation, reorientation, and secretion is completed in 2–3 min and is followed immediately by violent blebbing of the target cell, indicating that the death process has begun. Isolation of membrane fragments after the killing event shows numerous membrane pores, suggesting that the killer cell has perforated the target membrane and that this event is a critical element in the cytolytic process (Figure 4).

How is the target cell killed and how is the killer cell protected from its own killing molecules? Before we can answer this question, we must study what is being secreted in the form of granule exocytosis to cause this violent and rapid demise of the target cell.

COMPOSITION OF CYTOLYTIC GRANULES OF CTLS AND NK CELLS

Given that cytolytic granules are granulosomes they contain typical lysosomal components such as

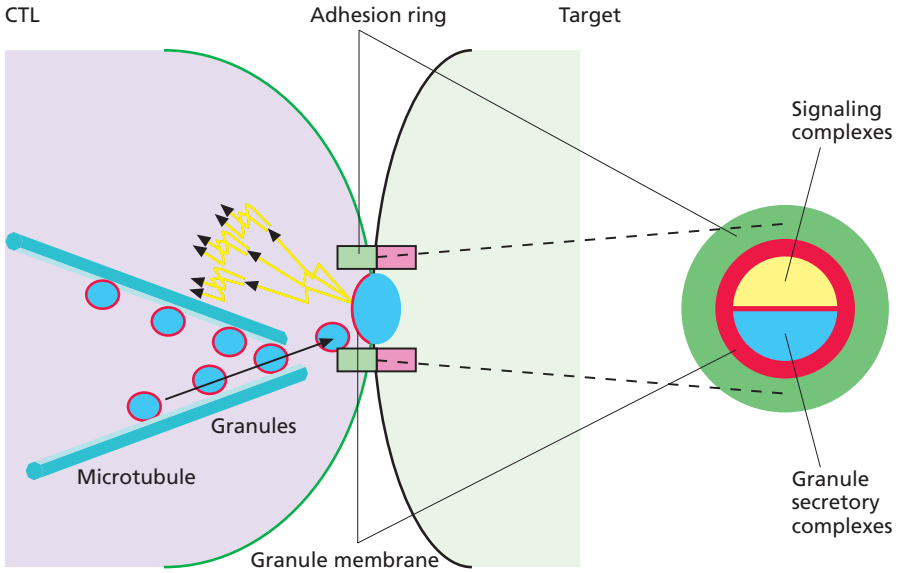

Figure 3 *Cytolytic synapse: the adhesion ring is depicted in side view (left) and en face (right panel). Inside the adhesion ring the localization of granule components and signaling components is shown. The granule membrane, lining the synapse on the cytotoxic lymphocyte (CTL) side, is shown in red.*

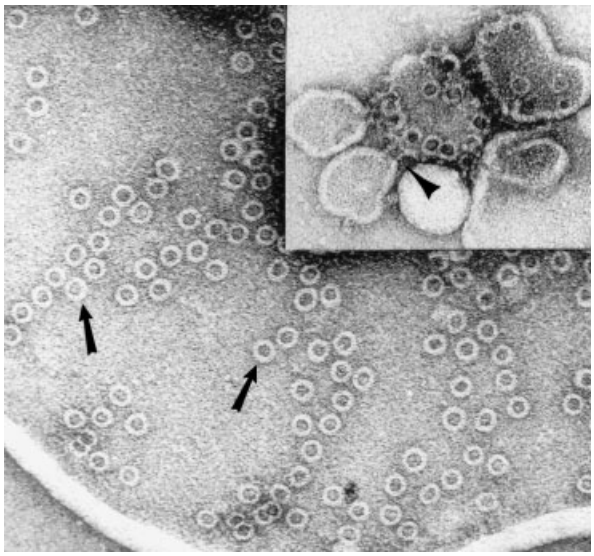

Figure 4 *Poly-perforin complexes on target membranes visualized by negative staining electron microscopy. Arrow: complex seen in top view; arrow head on inset: complex seen in side view (profile view).*

cathepsins, glucosaminidase, hexosaminidase, and other acid hydrolases. In addition granulosomes contain specific components not found in lysosomes that are designed for the killing process. The CTL and NK cell-specific components are perforin, the granzymes, Fas-L, granulysin, and serglycine as packing material.

Serglycine

Serglycine is a proteoglycan with a 14-kDa peptide core, which is heavily glycosylated with highly negatively charged chondroitin sulfate and heparan sulfate side chains, in a 250-kDa complex. Serglycine, similar to other granule proteoglycans, packed into dense highly concentrated packages allows condensation of granule contents, mainly granzymes and perforin. This effect is achieved through the formation of salt bridges between the negative charges of the proteoglycan, with positive charges on granzymes and perforin eliminating water molecules and reducing the colloid osmotic pressure. Granule contents are, then, large heteromultimeric complexes composed of the proteoglycan core with complexed perforin and granzymes, which are secreted en bloc.

Perforin

Perforin is a pore-forming protein sharing homology with complement components C6, C7, C8α, C8β, and C9 (Podack and Tschopp 1982; Henkart et al. 1984; Young et al. 1986; Podack and Kupfer 1991; Henkart 1997; Ponting 1999; Rukavina and Podack 2000; Smyth and Trapani 2001). The region of homology has been named the membrane attack complex/perforin (MACPF) domain; modeling studies suggest that this domain forms two amphipathic helices which are involved in transmembrane insertion and channel formation. Genome sequencing of several organisms has revealed additional MACPF-containing proteins and that the MACPF domain has been conserved from prokaryotes through plants and *Drosophila* spp. to the vertebrate system (Figure 5). Interestingly, the only prokaryotes containing proteins with MACPF domains to date are *Chlamydia pneumoniae* and *C. trachomatis*, both highly pathogenic organisms with intracellular localization.

Perforin is a 70-kDa protein synthesized as a hydrophilic, glycosylated monomer and it is directed from the trans-Golgi to the granulosome using as yet undefined targeting signals. Perforin on its C-terminus contains a C2 domain that is 100 amino acids long, which is characteristic for phospholipid-binding proteins (Jiang et al. 2001). On secretion and exposure to Ca^{2+} perforin binds to phospholipid head groups, triggering its ability to form multimers and insert itself into the hydrocarbon core of the membrane (Figure 6). Polymerization and membrane insertion have to go hand in hand, because, once polymerized, poly-perforin is unable spontaneously to insert into phospholipid bilayers. Perforin shares with the complement proteins above the remarkable biochemical ability to undergo a dramatic hydrophilic-to-amphiphilic transition which allows it to form transmembrane pores. The fully assembled pore is made up of about 20 perforin protomers, forming a tubular (cylindrical) complex that harbors a 16 nm-wide aqueous core. The poly-perforin cylinder is about 16 nm tall and inserted 4–6 nm deep in the membrane.

Perforin pores may be formed with as few as two or as many as 20 perforin molecules. Membrane pores allow the equilibration of ionic gradients, including Ca^{2+}, across the plasma membrane and result in the loss of membrane potential. Larger pores allow the efflux even of macromolecular cellular constituents. Membrane pores must be repaired, or else the cell would die via disruption of the normal cellular homeostasis. Membrane repair is achieved by endocytosis of the membrane patch containing the pore. The signal for the repair process comes from the Ca^{2+} influx across the pore. Endocytosis has two consequences: first, it is accompanied by pinocytosis of the liquid adjacent to the pore which will now be filling the endosome. As this liquid originates from the exocytosed granulosome and contains granzymes and other products, these components are now internalized in the target cell. Second, the pore formed by perforin persists in the endosome, interfering with acidification and normal endosome traffic, and may be responsible for endosomolysis which releases the endosome contents into the cytoplasm of the target cell where they initiate apoptotic and nonapoptotic cell death (Masson et al. 1986).

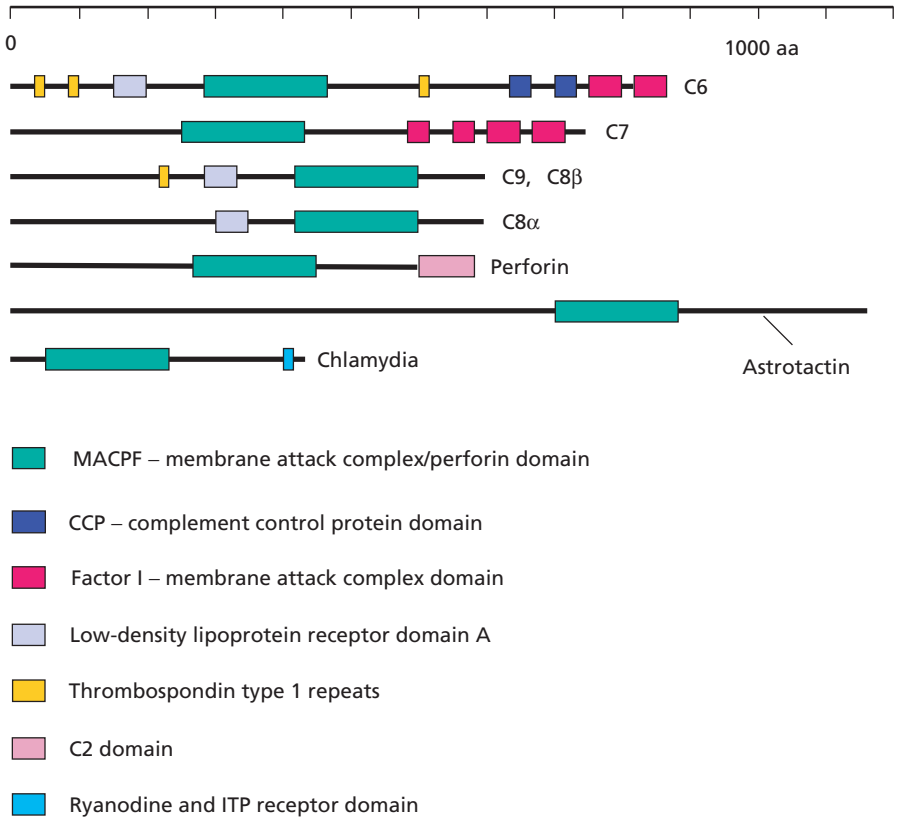

Figure 5 *Proteins sharing the membrane attack complex/perforin (MACPF) domain.*

Granzymes

Granzymes make up quantitatively the largest mass of the granule contents (Masson et al. 1986; Masson and Tschopp 1987; Shiver et al. 1992; Berke 1995; Beresford et al. 1997; Henkart 1997; Shiver et al. 1992; Darmon et al. 1996; Froelich et al. 1996; Atkinson et al. 1998; Kataoka et al. 1998; Metkar et al. 2002; Wallich et al. 2001; Zhang et al. 2001). Granzymes are serine esterases with narrow substrate specificities. They are transported to granulosomes by the mannose-6-phosphate receptor pathway typical for other lysosomal components including cathepsins, glycosylases, and other lysosomal enzymes. After exocytosis, granzymes gain entry into the target cell cytoplasm via perforin-dependent endocytosis and endosomolysis. In the target cytoplasm are the specific substrates for the granzymes. Granzymes always act in concert, depending on the collection of granzymes contained in the cytolytic granule. Humans have five granzymes, described below.

Granzyme B is a serine esterase with specificity of cleavage next to acidic (aspartate) residues (Masson et al. 1986; Masson and Tschopp 1987). Within the target cell it cleaves caspases and Bid (BH3 domain binding B-cell lymphoma [bcl]-2-like proapoptotic protein) and CAD (caspase-dominated DNAase) and sets off the apoptotic cascade including the mitochondrial pathway and the direct pathway of ICAD/CAD activation resulting in internucleasomal DNA cleavage and the generation of typical DNA ladders. The downstream activation of apoptotic mediators by granzyme B avoids some of the upstream regulators of apoptosis but is subject to blockade by bcl-2 and crmA. Granzyme B can bind to mannose-6-phosphate receptors expressed by certain cells and enter the cell by receptor-mediated endocytosis. However, in order for granzyme B to exit the endosome into the cytoplasm, perforin-mediated endosomolysis is essential.

Granzymes A and K (Masson et al. 1986; Masson and Tschopp 1987; Nakajima et al. 1995; Mullbacher et al. 1996; Beresford et al. 1997; Wilharm et al. 1999; Davis et al. 2001; Fan et al. 2002) are esterases with specificity for basic residues (arginine, lysine). They enter the target cell in a perforin-dependent process together with granzyme B and other granule components. Granzyme A mediates target apoptosis, including membrane blebbing and disruption of the nucleus. However, caspases are not activated and DNA laddering is not observed. Instead single-stranded DNA breaks are responsible for DNA breakdown. Granzyme A interacts with the nucleosome assembly complex that is involved in altering chromatin structure, to make it accessible for transcription and for single-stranded DNA excision-repair enzymes. It appears that the last activity is altered

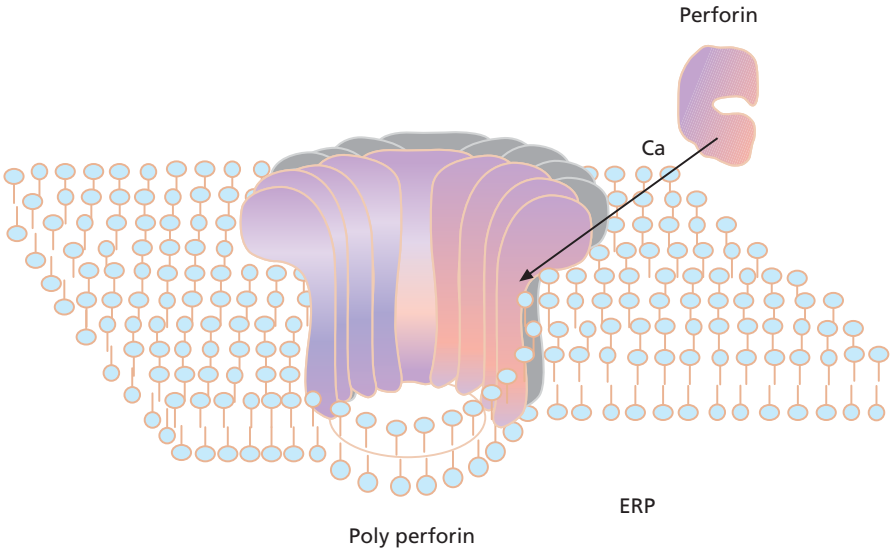

Figure 6 *Schematic view of perforin binding to phospholipid via Ca^{2+} and inserting itself as polymeric complex into the lipid bilayer.*

by granzyme A and results in single-stranded DNA breaks. Although granzyme K has similar enzymatic specificity to granzyme A, it is not known what its intracellular substrates are.

Granzymes H and M have chymotryptic specificity, with granzyme M also cleaving next to methionines. Granzyme H is expressed primarily by CTLs whereas granzyme M is exclusively expressed by NK cells. Granzyme H has been reported not to mediate cell death or apoptosis on internalization by target cells. Its function, similar to that of granzyme M, remains to be defined.

Mice, in addition to granzymes A, B, K, and M, express granzymes C, D, E, F, and G, but not granzyme H. This greater polymorphism suggests that mice have to combat a larger array of intracellular pathogens than humans.

Granulysin

Granulysin is found only in human granules. It is distantly related to saponins and has antibacterial activity for mycobacteria. It acts via membrane association and disordering of the lipid bilayer through ionic interaction. On delivery into cells it has specificity for mitochondria and triggers apoptosis and disrupts electron transport.

Fas ligand

Fas-L mediates apoptosis on Fas engagement by activation of caspase 8, and is the classic apoptotic mediator (Takahashi et al. 1994; Nagata and Suda 1995; Nagata 1996; Kataoka et al. 1998; Nagata 1998; Bossi and Griffiths 1999; Barry and Bleackley 2002). Apoptosis is a carefully regulated process subject to multiple regulatory checkpoints. Fas-L has two different localizations for expression. In granulosome-containing CTLs Fas-L is routed from the Golgi to the granule. The targeting information is contained in the proline-rich intracellular domain of Fas-L. In other cells Fas-L is found on the cell membrane. This distinct distribution explains why Fas-L killing of targets by CTLs is MHC restricted because it is exocytosed similar to or together with granule exocytosis only on appropriate signaling by the TCR. In other cells the surface expression of Fas-L allows triggering of apoptosis in Fas-carrying cells without additional triggering. The presence of Fas-L in cytolytic granules links this apoptotic mechanism directly to granule exocytosis.

KILLER CELL SELF-PROTECTION

How is the CTL or NK cell protected from perforin and the highly toxic molecules secreted during the cytotoxic event? First, the microanatomy of the cytolytic synapse confines the action of perforin and directs it toward the target membrane. The adhesion ring around the synapse is so dense that lateral diffusion will be restricted. Therefore, only the granule membrane lines the synapse on the CTL side. It is likely that the granule membrane is impervious to perforin action, and this hypothesis has recently been attributed to cathepsin B which is found coating the granule membrane and not allowing perforin to insert (Balaji et al. 2002). Second, the half-life of perforin after exposure to Ca^{2+} is very short and measured in seconds, because Ca^{2+} induces polymerization and polymerized perforin is not membrane active. Polymerization and membrane insertion have to proceed in a concerted action. Finally, CTLs and other hemopoietic cells express many serpins. Serpins are serine protease inhibitors first described and analyzed in serum

as trypsin and thrombin inhibitors. They form 1:1 covalent complexes with the protease that are resistant to dissociation by denaturing agents. Serpins are highly specific substrates for the respective serine protease. On cleavage of a loop in the serpin, a dramatic and rapid conformational change takes place in the serpin molecule, which distorts the active site of the protease to such an extent that the cleavage dissociation reaction cannot take place and the protease remains trapped in the complex. PI-9 is a human intracellular serpin, expressed by killer cells, dendritic cells, and other hemopoietic cells, that inhibits granzyme B with high specificity (Hirst et al. 2001). Surprisingly, although caspases and granzyme B have similar substrate specificities, PI-9 is a much better inhibitor for granzyme B than for caspases. In the mouse at least six additional serpins have been identified, and it is likely that there may be a specific serpin for each of the granzymes described above.

TARGET CELL DEATH

CTL- and NK cell-mediated killing unleashes several cell death pathways simultaneously via the granule exocytosis mechanism (Figure 7). The mechanism by which perforin mediates entry of other granule components into the target cytoplasm may be compared with a very sophisticated injection mechanism entailing plasma membrane pore formation and endosomolysis. Receptor-mediated endocytosis of granule contents is also possible but perforin is still required to liberate the granule contents and allow their exit into the cytoplasm where they mediate destruction. The following events, each potentially leading to death, occur contemporaneously upon granule exocytosis:

- Perforin pore formation alone, if extensive enough, can kill cells. More commonly, however, perforin is the catalyst for uptake of granule components and their release into the target cytoplasm.
- Granzyme A mediates cell death by single-stranded DNA breaks, and interference with DNA repair and nucleosome assembly.
- Granzyme B results in caspase and Bid cleavage, setting off two apoptotic cascades that result in CAD activation and DNA laddering.
- Granzymes H, K, and M (NK) are likely to contribute to cell death although their mode of action is as yet unknown.
- Granulysin sets off mitochondrial death and disruption of energy generation by associating with the outer mitochondrial membrane.
- Not studied yet are the effects of typical lysosomal constituents, including acid hydrolases which presumably gain entry into the target cell and may well have lethal effects.
- Finally, in concert with perforin and the pathways depending on it, Fas-L is exocytosed and gains surface expression to engage the Fas receptor in order to trigger conventional apoptosis; the Fas ligand pathway, in contrast to the molecular pathways described above, is not dependent on the availability of perforin.

This listing, presumably still incomplete, shows the barrage of biological weapons brought to bear on the annihilation of target cells. Target cells are recognized because they are parasitized by viruses or oncogenes that strive to evade death and to make the target noncompliant to normal apoptotic signals. By employing multiple death pathways it will be very difficult for the virus, or other parasite, to block all pathways simultaneously, and noncompliance can be overcome by the killer cell.

ROLE OF PERFORIN IN THE INDUCTION OF CTL ACTIVATION

CTLs and NK cells are effector cells mediating effector responses in the efferent arm of immunity by killing target cells via perforin and producing cytokines, principally IFN-γ (Beresford et al. 1997; Bossi and Griffiths 1999; Smyth et al. 2000; Haddad et al. 2001; Hirst et al. 2001). Both cytotoxicity and IFN-γ production are essential for tumor rejection and viral clearance. However, perhaps surprisingly, cytotoxic activity mediated by NK cells is also required in the afferent arm of immunity for induction of CTL responses. Two mechanisms have been defined: (1) CD70-expressing tumor cells are killed by NK cells via CD27 engagement. Killing by NK and IFN-γ production is absolutely required for the induction of a CTL response and establishment of tumor-specific memory (Smyth et al. 2001; Kelly et al. 2002). (2) Heat shock proteins are released on trauma or necrosis and chaperone peptides including potential antigens. Dendritic cells and macrophages have receptors for heat shock proteins, thereby endocytosing the molecules along with bound peptides. The peptides are channeled into the class I MHC antigen-presenting pathway and are available for CTL recognition. However, T-cell activation requires the presence of NK cells and the action of perforin and IFN-γ. In the absence of perforin-containing NK cells, a CTL response does not ensue; NK and dendritic cells undergo reciprocal activation which is needed to permit T-cell activation and clonal expansion.

PERFORIN FUNCTION IN HOMEOSTASIS

During and after an immune response T cells need to expand and contract rapidly, respectively. Clonal contraction is part of the homeostatic regulation required to maintain a balanced T-cell repertoire. Fas and Fas-L, other tumor necrosis factor (TNF) receptors, and cytokines participate in homeostatic regulation of T

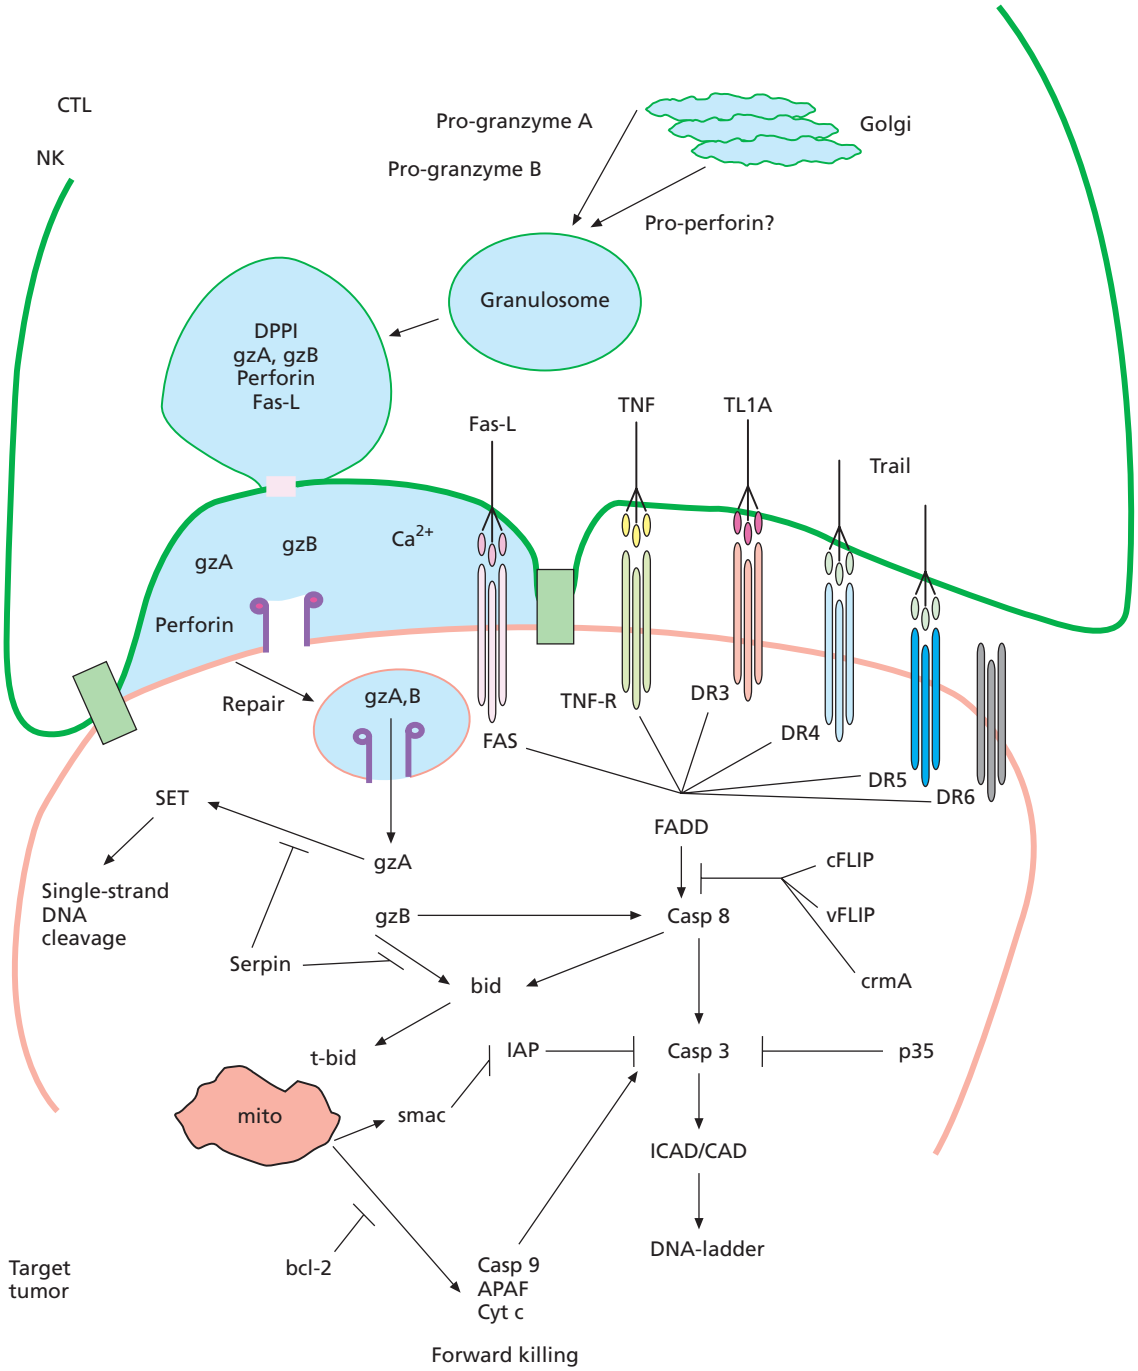

Figure 7 *Granule-mediated target killing: events in the target cell. See text for abbreviations.*

and B cells. Cytotoxicity mediated by perforin and associated with granules is required for homeostasis of CD8 CTLs and monocytes/macrophages. This function of perforin is seen only after viral challenge or in combination with other genetic defects. In murine models, the combined deficiency of perforin with Fas-L or Fas is much more severe than that of Fas-L or Fas deficiency alone (Spielman et al. 1998). Perforin/Fas-L deficiency results in early death and organ infiltration with CD8 cells and macrophages, indicating a critical role for perforin in their homeostasis (Figure 8). Similarly, perforin deficiency in humans causes childhood death by lymphoproliferation of CD8 cells and macrophage-type cells called histiocytes (see below) (Stepp et al. 1999; Fadeel et al. 2001). Homeostatic dysregulation in perforin deficiency is noted only after repeated antigenic (viral) challenge, suggesting dysregulation of the memory CTL pool.

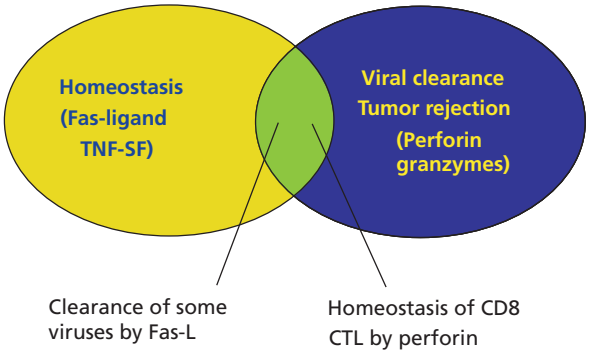

Figure 8 *Diagram of separate functions of perforin and Fas ligand (Fas-L) in immune defense and homeostatic regulation. Overlapping function in clearance of some viruses by Fas-L, and homeostatic regulation of CD8 cytotoxic lymphocytes (CTLs) by perforin.*

HOMEOSTATIC FUNCTION OF FAS AND FAS-L

Fas-L can induce apoptosis in Fas-expressing cells. Fas or Fas-L deficiency in mice results in lymphoproliferation and grossly enlarged lymph nodes by 6–12 months of age (Nagata and Suda 1995). Lymphoproliferation can be associated with autoimmunity in certain genetic backgrounds. The largest group of expanded T cells is found in the CD4/CD8$^-$, B220$^+$ population. Cells of the monocyte/macrophage lineage are only moderately expanded. Fas and Fas-L are important for antigen-induced cell death during secondary stimulation of T cells, and are believed to facilitate and maintain peripheral tolerance of T cells for self-antigens. CD4 cells are more susceptible to Fas-L-mediated deletion than CD8 cells, and Fas/Fas-L may be more important for CD4 T-cell homeostasis than for CD8 T cells. In humans, mutations in Fas or Fas-L give rise to autoimmune syndromes. The dysregulated removal of activated T cells results in the maintenance of selfreactive cells causing autoimmunity. It is not clear at the current time which cell types need to express Fas-L to maintain homeostasis; candidates are T cells or antigen-presenting cells.

GENETIC DEFECTS OF CYTOTOXICITY

Perforin deficiency in mice

Perforin is constitutively expressed in NK cells, NK-T cells, and γδ-T cells, all of which comprise a segment of the innate immune system. Although NK-T and γδ-T cells have TCRs, the TCR chains are relatively invariant and do not recognize MHC peptide complexes, although they recognize relatively invariant MHC class Ib molecules in association with lipids or carbohydrates. In αβ-T cells perforin is induced on T-cell activation and clonal expansion. The site with the highest level of perforin expression under physiological conditions is the decidua in the pregnant uterus. The decidua is enriched with decidual NK cells which express very high levels of perforin and may contribute to protection against infection. Perforin deficiency in mice that are kept free of pathogens has no obvious phenotype and does not disrupt the process of a normal pregnancy. However, on viral challenge perforin-deficient mice exhibit increased morbidity and mortality, emphasizing the importance of perforin in protection from viral infection. Perforin-deficient cells exhibit normal clonal expansion and tissue infiltration; however, viral clearance is impaired in the absence of perforin. Perforin is thus critical for the cytolytic process in vivo that eliminates the viruses. Perforin-deficient CTLs and NK cells in vitro have greatly diminished cytolytic activity and are only able to induce apoptosis in targets via Fas-L, TNF, or TNF-related apoptosis-inducing ligand (TRAIL) (Kagi et al. 1996).

Perforin-deficient mice develop spontaneous tumors with high incidence, lymphomas, and adenocarcinomas of the lung, indicating that perforin is important for immune surveillance against spontaneous tumors (Smyth et al. 2000; Smyth and Trapani 2001). Perforin-deficient mice are unable to reject challenge with immunogenic tumors when compared with wild-type mice. Controlled treatment with carcinogens demonstrates a higher frequency and earlier incidence of tumors in perforin-deficient mice in comparison to wild-type mice (van den Broek and Hengartner 2000; van den Broek et al. 1996). It is evident from these observations that perforin is an important mediator of tumor immunity.

Perforin is frequently found expressed at sites of autoimmune reactivity. Accordingly perforin deficiency can ameliorate certain autoimmune states, e.g. perforin-deficient non-obese diabetic (NOD) mice have a much lower and later incidence of diabetes than perforin-sufficient NOD.

Allogeneic bone marrow transplantation is complicated by the development of graft-versus-host disease arising from grafted T cells activated by the recipient's alloantigens. By transplanting perforin-deficient T cells the onset of graft-versus-host disease is dramatically delayed but then sets in with full force and lethality, suggesting that perforin contributes to the initiation of the immune response (Baker et al. 1996, 1997; Jiang et al. 2001). In allogeneic organ transplantation, perforin-expressing cells are found during transplant rejection. However, perforin deficiency does not noticeably affect organ rejection, indicating multiple redundant pathways (Atkinson et al. 1998; Kataoka et al. 1998; Ponting 1999).

Perforin-deficient mice have an impaired ability to downregulate CTLs on chronic infection and repeated in vivo stimulation, indicating a participation of perforin in CD8 CTL homeostasis (Edwards et al. 1999; Harty et al. 2000). This is more apparent when perforin deficiency is

combined with Fas or Fas-L deficiency. Perforin/Fas-L double-deficient mice die at about 10 weeks of age of an autoimmune syndrome characterized by organ infiltration with macrophages and expansion of CD8 and CD4 cells, with an inversion of the normal CD4:CD8 ratio (Spielman et al. 1998). The mechanism by which perforin contributes to CTL downregulation is not clear, but two hypotheses have been discussed:

FRATRICIDE

On CTL killing of target cells, the CTLs can pick up target antigens, process the antigens, present them via MHC-I, and thereby become a target itself for other CTLs. In the presence of perforin CTLs would kill each other and thereby downregulate their activity.

KILLING OF ANTIGEN-PRESENTING CELLS

CTL activation and clonal expansion is mediated by antigen-presenting cells. On acquisition of cytotoxicity CTLs are perfectly able to kill antigen-presenting cells, thereby removing the initial signal for their own generation. In the absence of perforin the elimination of antigen-presenting cells is impaired, thereby providing chronic stimulation of CTLs and disruption of CTL homeostasis.

PERFORIN DEFICIENCY AND DEFECTS IN CYTOTOXICITY IN HUMANS

The syndrome of familial hemophagocytic lymphohistiocytosis (FHL) is a lethal inheritable disease associated with dysfunctional cytotoxicity of NK cells and CTLs (Stepp et al. 1999). The disease is characterized by early childhood onset, frequently after viral infections, and accompanied by lymphocytic proliferation and infiltration of tissues with histiocytes. The last cell type represents a late-stage monocyte/macrophage-derived cell characteristic for this syndrome. Recently, several etiological causes of the syndrome have been identified and can be subgrouped into several categories.

About 30 percent of the cases of FHL are caused by perforin deficiency. The remaining cases come from several disorders associated with dysfunctional secretory lysosomes, including granulosomes. Secretory lysosomes are found in lymphocytes and NK cells, granulocytes, mast cells, platelets, and melanocytes. Dysfunction of the secretory or trafficking pathway of secretory lysosomes may therefore affect other cellular systems, in addition to the cytolytic machinery.

The Chédiak–Higashi syndrome is an autosomal recessive disorder causing hypopigmentation of the skin, eyes, and hair, prolonged bleeding times, recurrent infections, abnormal NK cell function, and peripheral neuropathy. Morbidity results from patients succumbing to frequent bacterial infections or to lymphoproliferation. The *CHS1/LYST* gene encoding a cytosolic protein of 430 kDa is dysfunctional. The exact function of this gene is not known except that it participates in the biogenesis/secretion of secretory lysosomes. A similar defect is found in Beige mice. NK cells and polymorphonuclear granulocytes (Figure 9) have grotesquely enlarged granules which, however, cannot be secreted and hence NK cell activity is diminished. The inability of granule secretion is associated with the inability to use perforin for killing and in this regard appears as functional perforin deficiency with the same consequence of hemophagocytic lymphohistiocytosis resulting in death.

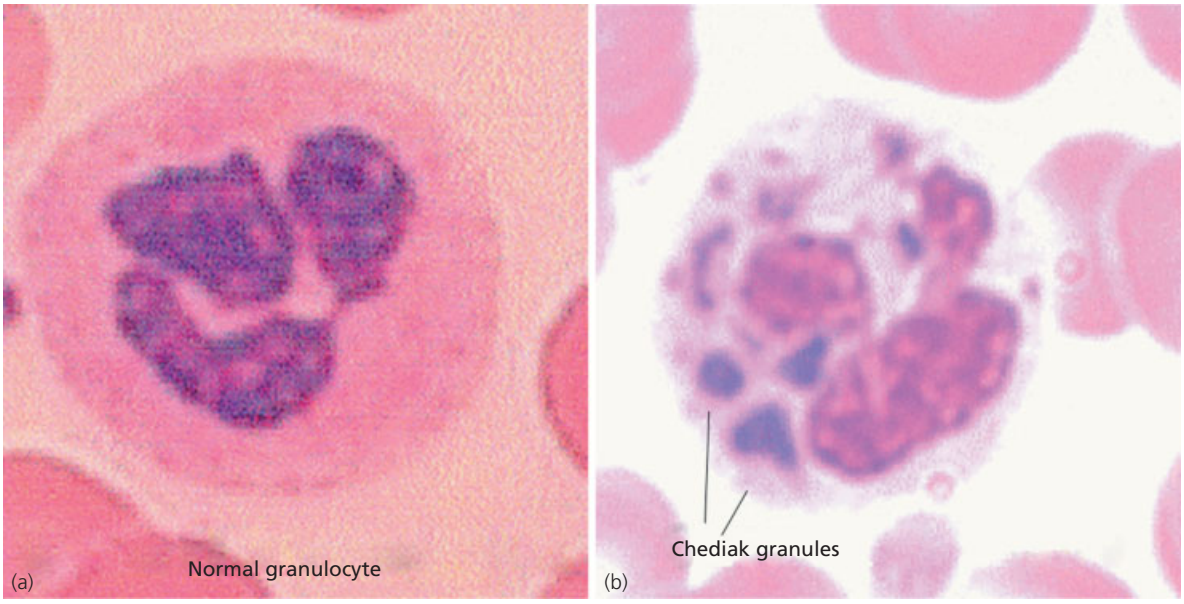

Figure 9 *Gigantic granules in Chediák–H igashi syndrome.* **(a)** *Normal granulocytes.* **(b)** *a polymorphonuclear granulocyte with enlarged granules is shown.*

Griscelli's disease is an autosomal recessive disorder associated with hypopigmentation and occurrence of acute phases of uncontrolled lymphocyte and macrophage activation, ultimately causing death. Several genetic variations of the disease exist. One form of the disease is caused by mutations in Rab27a, a protein involved in vesicle traffic and required for granule exocytosis in lymphocytes and for melanocyte function. Evidence in Ashen mice suggests that Rab27b can substitute for Rab27a, but that Rab27b is not expressed in lymphocytes and melanocytes. CTL granules appear normal in Griscelli's syndrome; they migrate to the cytotoxic synapse; exocytosis does not take place, however, as a result of the absence of Rab27a (Haddad et al. 2001; Stinchcombe et al. 2001).

Patients with Hermansky–Pudlak disease have primarily bleeding abnormalities and ocular albinism. The syndrome includes mutations of at least three different gene products affecting vesicular traffic. One of the mutations in the Rab geranylgeranyl transferase α subunit reduces Rab prenylation and is responsible for defects in platelet granule synthesis. Cytolytic CTL granules fail to polarize properly, although their exocytosis appears normal. The murine model for this disease is found in gunmetal mice.

GRANZYME DEFICIENCIES

Granzyme deficiencies have been created in mice by gene targeting but so far have not been described in human populations. Granzyme A and granzyme B deletions have been described in the literature (Pham and Ley 1997; Simon et al. 1997). However, as granzyme B is on the same chromosome with, and upstream of, granzymes C, D, E, and F, the insertion of a neocassette also inactivated downstream granzyme expression. Re-examination of the granzyme B targeting using the Cre/lox system showed that most of the effects attributed to granzyme B knockout may have been caused by the concurrent extinction of granzyme C.

Granzyme A-deficient mice have no overt phenotype and no defect in the cytotoxic activity of T and NK cells. Similarly, granzyme B-deficient mice appear normal and their cytotoxic activity in vitro is not diminished. However, when DNA release is measured by using granzyme A- or B-deficient CTLs a reduction and delay in DNA release is observed, indicating impaired DNA degradation.

As mentioned above, it is likely that granzymes have evolved to defeat viral escape mechanisms. Therefore it might be expected that granzyme deficiencies may be associated with increased susceptibility to certain viral infections and mortality. Indeed, by titrating the viral dose and measuring disease and mortality, an important function for granzymes in antiviral defense can be demonstrated. Ectromelia is the mouse pox virus which is highly virulent in mice. Wild-type mice are susceptible to infection, but lethality requires an infective dose of more than a million viral units. Perforin-deficient mice are highly susceptible and succumb to disease from as little as one viral unit. Granzyme A- and B-deficient mice exhibit susceptibility between these two extremes (Mullbacher et al. 1996, 1999). Interestingly, the ability to clear virus infection and to reject tumors does not correlate (Table 1). Although granzymes clearly are important for viral protection they seem to be dispensable for tumor rejection. RMAS is an MHC-negative tumor that requires NK cells for rejection whereas the K1735 melanoma is rejected by CTLs. In both cases and in immune surveillance against methylcholanthrene-induced carcinomas, perforin is required but granzymes A and B are not.

DPP1 DEFICIENCY (CATHEPSIN C)

Dipeptidyl peptidase is required for the cleavage of the pro-dipeptide of all granzymes. In the absence of this cleavage granzymes remain inactive as zymogens. CTLs with deficiency of the dipeptidyl peptidase have the hallmarks of combined granzyme A/B deficiency. However, dipeptidyl peptidase is also important for activation of proteases in mast cells, granulocytes, and other cells. In humans dipeptidyl peptidase deficiency, the Papillon–Lefevre syndrome, or keratosis palmoplantaris with periodontopathia is an autosomal recessive disorder. Patients suffer early loss of teeth, apparently from chronic infection of the periodontium.

Table 1 *Role of perforin and granzymes in viral clearance and tumor rejection*

Deficiency	Lethal viral dose (mouse pox virus)	Rejection of RMAS tumor	Rejection of K1735 melanoma	Immune surveillance, carcinogenesis
Wild type	$>10^6$	Yes	Yes	Normal
Perforin	1	No	No	Impaired
Granzyme A	10^5	Yes	Yes	Normal
Granzyme B[a]	10^4	Yes	Yes	Normal
Granzyme A + B[a]	1	Yes	Yes	Normal

a) Granzyme B deficiency includes cluster deficiency.

Cytotoxicity and antiviral defense

Viruses are intracellular parasites infecting the victim's own cells. Antibodies and pattern recognition receptors used for recognition and defense against extracellular parasites, primarily bacteria and bacilli, are not much use against intracellular parasites, which can be removed only by the destruction of the infected cells. This is achieved in two ways: by suicide (apoptosis) of the infected cell and, in the case of failure of suicide, by the cytotoxic lymphocyte (Mullbacher et al. 1996; Edwards et al. 1999; Harty et al. 2000; Wallich et al. 2001).

A primary defense system against viral spread is the interferon system. Double-stranded RNA or DNA of the viruses is recognized by DNA- or RNA-dependent protein kinase which turns on INF-α and -β with the resultant interferon secretion signaling via interferon receptors to the infected and neighboring cells. The signals result in shutdown of protein synthesis and transcription of antiviral genes that block viral replication and viral clearance, or in apoptosis of the infected cell. Many virus infections are contained at this stage. Other viruses have evolved to overcome the initial antiviral response and block apoptosis of the infected cell. The interferon secretion, however, also activates NK cells which are attracted and activated and begin killing infected cells that fail to undergo apoptosis. It is apparent that successful killing must overcome the anti-apoptotic activities of the virus that have allowed it to begin to replicate. How does the NK cell recognize the infected cell? First, some viruses downregulate MHC molecules to avoid T-cell detection; this is the signal for NK cells to start killing such cells. Second, infected cells frequently express new gene products (stress genes, e.g. Rae-1β) that are recognized by positively signaling receptors on the NK cell (NKG2D) and initiate cytotoxicity. NK cell killing and antigen release, together with IFN-γ production, bring dendritic cells to the site of action. Dendritic cells further activate NK cells and recruit the CTL response. The fact that the virus has survived in the infected cell up to this point is testimony to its ability to block apoptotic pathways. The virus now needs to focus on evading detection by NK and T cells and/or to block the cytotoxic assault. Herpes viruses have very large genomes devoted largely to the purpose of evading immune recognition and to thwarting the cytotoxic response. Indeed many herpes viruses are never totally eliminated and persist as latent infections that can flare up at any time that the CTL response is suppressed by medical immune suppression or other natural causes. Pox viruses focus on blocking cytotoxicity; they express powerful inhibitors for caspases (crmA) and granzymes (serpin homologues). However, the evolution of several granzymes in the arsenal of the cytotoxic response seems to be the response to this family of viruses allowing survival of the host, even though with great difficulty.

It is self-evident that only those species able to resist and overcome viral attack were able to survive and reproduce, and likewise that viruses had to continue to evolve new strategies to prevent obliteration. This struggle continues today, best exemplified in the HIV epidemic and the trend of new viruses emerging.

CYTOTOXICITY AND ANTI-TUMOR DEFENSE

Perforin is a critical part of immune surveillance against spontaneous tumors and protection against carcinogens. In addition perforin is required for the rejection of tumors by NK cells and CTLs whereas granzymes appear dispensable. One might conclude that it is easier to kill tumor cells than virus-infected cells. So, then, why are tumors not eliminated by the immune system? The answer is that the tumor has developed elaborate pathways to evade or suppress the immune system. Tumors do not secrete interferons that would alert the NK response; indeed the lack of an interferon response makes many tumors susceptible to viruses that are easily suppressed by normal cells. The lack of arousal of an NK response seriously hampers the harnessing of dendritic cells and a CTL response. The lack of signals emanating from the tumor also prevents CTLs from homing in on the tumor. The tumor, unlike viral infection, is not perceived by the immune system as dangerous. Again, unlike viral infection and replication, tumor progression and stepwise mutation are slow. Tumors express many negative regulators of the immune response. CTL responses to viruses entail a rapid burst of clonal expansion followed by an equally rapid clonal contraction, leaving behind a few memory cells that can respond again and faster in a second viral attack. The clonal contraction, mediated for CD8 CTL cells by perforin and for CD4 cells by Fas-L, is absolutely necessary to avoid autoimmunity and lymphoproliferation. Tumors express genes that can interfere with clonal expansion and/or cause premature clonal contraction and downregulate cytotoxic activity, thereby allowing their continued survival. The challenge for tumor immunologists is the ability not only to develop vaccines that generate activated NK cells and specific CTLs, but also to find ways to direct these cells to the tumor site.

Immunological memory

SHANE CROTTY AND RAFI AHMED

History of vaccination	1	Maintenance of immunological memory	9
Protective immunity	3	Conclusion	12
Memory T- and B-cell differentiation	4	References	13

The primary function of the immune system is to defend against microbial pathogens. It accomplishes this task at two levels: first, by generating a specific immune response against the invading pathogen and controlling the infection; and second, by remembering this first encounter and mounting an accelerated immune response upon re-exposure to the same pathogen. This rapid recall response can either completely prevent disease or greatly lessen the severity of clinical symptoms. The first documentation of 'immune memory' dates back to the time of the Greek historian Thucydides, who recorded that the 'same man was never attacked twice' while describing the plague of Athens in 430BC (Finley 1951). It is remarkable that we knew nothing about the immune system or about microbes when Thucydides made his astute observations on immune memory; it would be more than 2000 years before we gained an appreciation of the immune system and learnt that microbes cause infectious diseases. However, it is now well established that memory and specificity constitute the two defining features of adaptive immune responses.

The focus of this chapter is on the principles of immune memory. This chapter is divided into four parts: (1) a historical perspective of vaccination; (2) an overview of protective immunity to microbes; (3) a discussion of the current models of memory T- and B-cell differentiation; and (4) an overview of the mechanisms involved in maintaining immunological memory.

HISTORY OF VACCINATION

Immunological memory is the basis for vaccination; the discipline of vaccinology originated from the observation that previous exposure to a disease conferred resistance to a subsequent episode. Thus, the principle of vaccinology was that, if somehow the first episode of a disease could be attenuated, one would be protected against the more severe form of the disease. The earliest recorded attempts to put this into practice were made in China and India around AD 1500 when pustular material from smallpox patients was inoculated into healthy people (Fenner et al. 1988). This process, called 'variolation', caused smallpox but, for reasons that are not fully understood, the disease was usually milder. More importantly, 'variolated' individuals were protected against naturally acquired smallpox. However, this approach did not gain popularity and was eventually discontinued because the degree of morbidity and mortality associated with variolation was simply too variable and too high to be acceptable.

The major breakthrough came with the classic experiments of Jenner in 1796. Jenner had noticed that milkmaids who were commonly infected with cowpox were spared the ravages of smallpox. Jenner reasoned that inoculation of cowpox pustular material might prevent smallpox. In many ways, vaccinology was born in 1796 when Jenner inoculated young James Phipps with cowpox virus and subsequently prevented smallpox, thereby showing that exposure to a related but less pathogenic virus could confer protection against a more virulent virus. However, despite this remarkable achievement, the field of vaccinology stood still for the next 50–75 years. This lack of progress was primarily the result of the fact that it was still not proven that microbes caused smallpox, or any disease. Thus, there was no clear scientific basis for developing additional vaccines.

Things changed dramatically in the second half of the nineteenth century as a result of the pioneering work of Pasteur, Koch, Ross, von Behring, Ehrlich, and others. These scientific giants not only proved that microbes cause infectious diseases, thus laying the foundations of immunology and microbiology, but their work also resulted in the development of successful vaccines against rabies, typhoid, cholera, plague, and diphtheria (Plotkin and Orenstein 1999). It is only fitting that the first Nobel Prize in Medicine and Physiology, given in 1901, was awarded to von Behring for his work on diphtheria. Several additional vaccines were developed during the first half of the twentieth century, including the highly effective yellow fever virus vaccine by Theiler, for which he was awarded the Nobel Prize in 1951.

Until 1950 all viral vaccines were prepared in either mammalian or avian whole tissues. In that year Enders and colleagues showed that viruses can be grown in vitro in cell culture, which opened enormous scientific possibilities and facilitated the development of many of our currently used vaccines (Table 1), including vaccines against polio virus, measles, mumps, and rubella. This technology continues to be the most common method of manufacturing viral vaccines to this day.

Major advances have occurred during the past 25 years in our ability to 'cut and paste' genes, yet only two currently licensed vaccines are made using recombinant DNA technology – the hepatitis B vaccine and the Lyme disease vaccine. However, it is expected that almost all future vaccines will rely on recombinant DNA technology to some extent. A multitude of expression vectors (bacterial, viral, 'naked' DNA) have been developed and considerable effort has gone into optimizing their in vivo expression and methods/routes of immunization (Table 2; see Part VII: Vaccines). It is likely that these will become the main technologies for our future vaccines. Indeed, several recombinant vaccines are currently in human clinical trials. It remains to be seen which of these vectors will prove to be the most effective. The crucial properties will be the ability to target antigen-presenting cells (APC), the level and duration of gene expression in vivo, the ease of constructing the vector, and issues such as cost and safety of the vectors.

Table 1 *General approaches for vaccines*

Type of vaccine	Comments	Examples	
		Viral	Bacterial
Live attenuated organism	The organism is attenuated such that it does not produce clinical disease but still retains sufficient immunogenicity and replicative capacity to induce protective immunity	Polio (Sabin, OPV), measles, mumps, rubella, yellow fever, varicella (chickenpox)	Bacilius Calmette–Guérin (BCG)
Killed organism	The vaccine consists of the whole organism, which has been chemically inactivated to prevent replication, but the immunogenic structure of the organism is preserved	Polio (Salk, IPV), influenza, Japanese encephalitis, rabies, hepatitis A	Pertussis (whole), cholera
Antigenically related organism	This is the strategy used by the original vaccine	Cowpox or vaccinia, for smallpox	None
Subunit vaccines	The vaccine consists of subcomponents of the organism. These subcomponents are usually either surface proteins of a virus, or proteins and/or polysaccharides of bacteria	Hepatitis B	*Haemophilus influenza*b, pneumococci, meningococci, typhoid, pertussis (acellular), Lyme disease
Antitoxins	The vaccine consists of inactivated toxin (toxoid) that is no longer toxic but still retains its immunogenic structure	None	Tetanus, diphtheria, anthrax
Vectored vaccines	These vaccines are currently in development. These strategies use known immunogenic and safe viruses or bacteria as engineered vectors to express immunogenic proteins from pathogens of interest (see Table 2)	None licensed, but several in phase I and II clinical trials	
Nuclei acid (DNA) vaccines	These vaccines are currently in development. The vaccine consists of plasmid DNA capable of expressing the antigen of interest when introduced into cells	None licensed, but several in phase I clinical trials	

Table 2 *Recombinant delivery systems for future vaccines*[a]

Delivery systems
Plasmid 'naked' DNA

PROTECTIVE IMMUNITY

There has been great interest in determining the relative importance of humoral versus cellular responses in protective immunity. This has resulted in much debate and considerable experimentation to assess the role of T- and B-cell responses in protection from reinfection. When examining this issue, one must remember that antibodies and T cells have evolved to perform entirely different functions. The business of antibodies is to deal with the microbe itself (i.e. free virus particles, bacteria, and parasites) and that of T cells is to deal with infected cells. As T cells can only recognize microbial antigens in association with host MHC molecules, the free virus particles or bacteria are invisible to them. Thus, antibody provides our only specific defense against free microbial organisms, and therefore the importance of pre-existing antibody in protective immunity against infectious diseases cannot be overemphasized. In fact, antibody is likely to be the sole mechanism of protective immunity against bacteria and parasites that have an exclusively extracellular lifestyle. However, the equation begins to change for viruses and for those bacteria and parasites that can survive or replicate intracellularly. Although antibody again provides the first line of defense against such infections, frequently the inoculum is not entirely neutralized by the pre-existing antibody. This is where the T cells come into play, because their main function is surveillance of infected cells. T cells are divided into two subsets, $CD4^+$ and $CD8^+$ T cells, and both of these subsets play a role in protective immunity. They do this by either killing the infected cell and/or by releasing cytokines that stop or slow growth of the microbe. In addition to these effector functions carried out by both $CD4^+$ and $CD8^+$ T cells, $CD4^+$ T cells also play an important role in providing help for antibody production and help for generating $CD8^+$ T-cell responses.

Thus, based on these basic principles, protective immunity to extracellular pathogens depends primarily upon B cells and $CD4^+$ T cells (as helpers), whereas a concerted effort by B cells, $CD4^+$ T cells (as both helpers and effectors), and $CD8^+$ T cells is required to control intracellular pathogens. Although this generalization is reasonably accurate, there are several examples where microbial infections have been controlled exclusively by antibody (i.e. passive antibody transfer) or by $CD8^+$ T cells (i.e. after immunization by a vaccine containing only the $CD8^+$ T-cell epitopes) (Ahmed and Biron 1999). These experiments clearly show that there are situations where either humoral or cellular immunity can be sufficient for protection. The correct conclusion from such experiments is that, in the given situation, just the $CD8^+$ T-cell response or the antibody response was adequate for protection. However, it is crucial to realize that it is misleading to conclude from this type of experiment that the missing response does not play a role in protective immunity. The danger of reaching such a conclusion is that potentially useful immune responses may get excluded from the design of a vaccine.

Similarly, when designing a vaccine it is prudent to look beyond the type of immunity generated during the natural infection, e.g. antibody plays a minimal role in controlling an acute primary lymphocytic choriomeningitis virus (LCMV) infection in mice, or in conferring protection from re-infection ($CD8^+$ T cells are the major players in both instances) (Buchmeier and Zajac 1999). Yet, passive transfer of neutralizing antibody can confer a reasonable degree of protection (Buchmeier and Zajac 1999). A similar situation exists for *Listeria monocytogenes*. *Listeria* species has long been considered to be an infection controlled exclusively by T cells, but a recent study has shown that antibody is also effective in eliminating it (Edelson et al. 1999). These findings have obvious implications for vaccine design, e.g. although very little neutralizing antibody is generated during the course of HIV infection, immunization with the right form of HIV envelope protein may induce neutralizing antibody that would be useful in conferring protective immunity (Mascola et al. 2000; Burton 2002). Thus, the right strategy for a HIV vaccine would be to stimulate both the humoral and cellular arms of the immune system.

What is the basis of protective immunity? Is it protection from infection or from disease? In the strictest sense, protection from infection would mean that there was sufficient pre-existing antibody to neutralize/opsonize all of the pathogen in the inoculum and there was no further amplification of the microbe. This is frequently referred to as sterilizing immunity. Does this ever happen? The precise answer is not known, but it is likely that it does happen regularly when the inoculum size of a pathogen is very low. However, when challenged with a substantial inoculum of pathogen, it is more likely that a substantial fraction of the virus/

bacteria gets neutralized and the remaining fraction that is able to initiate infection is quickly controlled by the rapid anamnestic response of memory T cells and/or memory B cells (Ahmed and Gray 1996; McChesney et al. 1997). Overall, this is a pretty good scenario. First, the infection is rapidly controlled and there is no disease; second, the virus is fully eliminated by the memory response; and third, this low-grade, transient, subclinical infection serves as a natural 'booster' to the immune system.

MEMORY T- AND B-CELL DIFFERENTIATION

Before considering models of memory B- and T-cell differentiation it is important to appreciate a fundamental difference between cellular and humoral immunity. Microbial infections usually induce both T- and B-cell long-term memory. However, the nature of T- and B-cell memory is different (Figure 1 and Table 3).

B-cell memory is usually manifested by continuous antibody production, even after resolution of the disease. Prolonged antibody production, lasting for several years after infection or immunization, has been observed in humans as well as in experimental systems (Scheibel et al. 1966; Simonsen et al. 1984; Kjeldsen et al. 1985; Cohen et al. 1994; Slifka et al. 1995; Bottiger et al. 1998; Crotty et al. 2003; Hammarlund et al. 2003). In contrast, the effector phase of the T-cell response is short-lived (a few weeks), and 'memory' in the T-cell compartment results from the presence of quiescent memory T cells, which are found at higher frequencies than naïve cells and can respond faster and develop into effector cells (i.e. cytoxic T lymphocyte (CTL) or cytokine producers) more efficiently than can naïve T cells (Kedl and Mescher 1998; Bachmann et al. 1999a; Cho et al. 1999; Zimmermann et al. 1999; Barber et al. 2003). This dichotomy in effector function in the humoral and cellular memory pools is a feature of most immune responses to immunizations or acute infections, and it makes teleological sense. Sustained secretion or overproduction of cytokines can have deleterious effects, and the presence of fully active killer memory T cells could result in severe immunopathological damage if some of these CTLs were crossreactive with selfantigens. Thus, maintenance of T-cell immunity by sustaining the effector phase would carry a high price tag. As memory T cells can rapidly develop into effectors and quickly gain access to sites of infection, it is not essential in most instances to maintain effector T cells to provide protection.

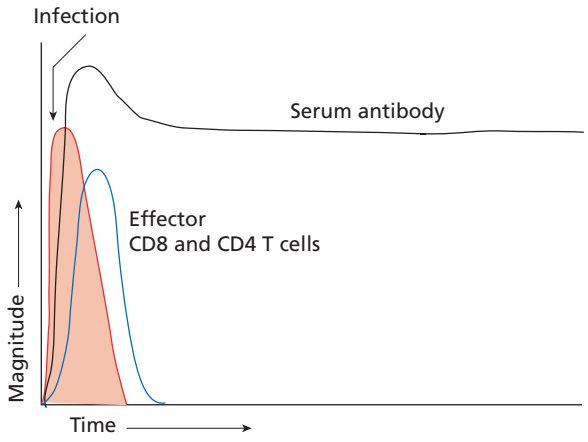

Figure 1 *The nature of effector T- and B-cell responses is different. Most microbial infections induce prolonged serum antibody responses that can persist for months or years after resolution of the infection. In contrast, effector T-cell responses (i.e. active killer cells and cytokine producers) are short-lived and are seen only during the acute phase of infection.*

Table 3 *Distinction between effector B and T cells*

Effector B cells
Plasma cells are end-stage-differentiated cells that constitutively produce antibody in the absence of antigen.[a] A proportion of plasma cells can live for extended periods in the bone marrow. These long-lived plasma cells are an important source of antibody in the serum and can also contribute to antibody in the mucosa. This pre-existing antibody forms the first line of defense against infection and is a key aspect of protective immunity against microbial infections
Effector T cells
Effector T cells secrete cytokines and can kill infected cells. In contrast to plasma cells, T cells maintain effector functions only in the presence of antigen. In the absence of antigen, effector T cells either die or differentiate into memory T cells. This also contrasts with plasma cells that are fully differentiated end-stage cells. Plasma cells do not give rise to memory B cells

a) Antigen is needed for differentiation of naïve or memory B cells into antibody-secreting plasma cells but is not required for maintaining antibody production by fully differentiated plasma cells.

B-cell memory

The two critical cell types involved in B-cell memory are memory B cells and plasma cells. The major differences in naïve B cells, memory B cells, and plasma cells are summarized in Tables 4 and 5 and the lineage interrelationships of these three cell types are shown in Figure 2. In this simple model, after the initial activation of naïve B cells (by antigen and T-cell help), activated B cells undergo clonal expansion. This initial proliferation is observable as histologically defined regions of B-cell clusters, known as extrafollicular foci, within the T-cell-rich areas of secondary lymphoid organs. During this initial phase of activation, B cells can class switch from IgM to IgG or other isotypes if stimulated strongly. In addition, it is generally thought that there is no or minimal somatic mutation/affinity maturation of the B-cell receptor at this stage of the B-cell response (Jacob and Kelsoe 1992; MacLennan

Table 4 *Differences between naive and memory B cells, in humans*

Naïve B cells	Memory B cells
No somatic mutation or affinity maturation of B-cell receptor	Somatic mutation and affinity maturation of B-cell receptor
Not isotype switched; mostly IgM^+ IgD^+	~40% isotype switched; ~60% IgD^-: 40% IgM^+ IgD^+ 40% IgG^+ or IgA^+, IgD^- 20% IgM^+ IgD-
$CD27^-$	$CD27^+$ More efficient antigen-induced proliferation? (Martin and Goodnow 2002)

1994); however, this has been challenged by a recent study in an autoimmune mouse model (William et al. 2002). Importantly, most of the antibody-secreting plasma cells generated from B cells in extrafollicular foci are thought to be short-lived, with a half-life of 3–7 days (McHeyzer-Williams 1997; Ho et al. 1986).

An important aspect of the model described in Figure 2 is affinity maturation of memory B cells and the generation of long-lived plasma cells. After the initial phase of B-cell proliferation and differentiation in extrafollicular foci, some B cells migrate back to the follicle (the B-cell regions of secondary lymphoid organs), and there is a second phase of clonal expansion of activated B cells within the specialized microenvironment of a germinal center (GC) (Jacob and Kelsoe 1992; MacLennan 1994; Tsiagbe and Thorbecke 1998). It is normally within the GCs that affinity maturation occurs, and B cells selected within the GC mature into memory B cells or plasma cells (Berek et al. 1985; Jacob et al. 1991). Additional class switching occurs in the GC. GCs contain antigen-specific CD4 T cells, and follicular dendritic cells (FDC) that retain depots of antigen for stimulation and selection of high-affinity B cells. Germinal center B cells proliferate rapidly (of the order of 6–7 h per division – Liu et al. 1991) and undergo positive selection by B-cell receptor binding to antigen attached to FDCs, as well as by B-cell interactions with antigen-specific CD4 T cells (Kosco et al. 1988; MacLennan 1994). A great deal of B-cell apoptosis occurs in GCs, as many of the B cells that undergo somatic hypermutation end up with nonantigen-specific or nonfunctional B-cell receptors (MacLennan 1994; McHeyzer-Williams et al. 2001; Ho et al. 1986).

There is evidence to suggest that plasma cells derived from high-affinity, isotype switched B cells tend to be longer-lived and reside in the bone marrow (Manz et al. 1997, 1998; Slifka et al. 1998). Teleologically, the basic model of a B-cell response generating short-lived plasma cells first and long-lived plasma cells and memory B cells later is appealing because, in an infection, it is valuable to get antipathogen antibodies produced as rapidly as possible (which is done by those antigen-specific B cells that differentiate into plasma cells early in extrafollicular foci). But it is also important to evolve high-

Table 5 *Differences between memory B cells and plasma cells*

	Memory B cell	Plasma cell
Location	Reside primarily in the secondary lymphoid organs	Reside primarily in the bone marrow
Function	Important for replenishing the pool of plasma cells and memory B cells. Do not actively secrete antibody, but respond to antigen by rapidly dividing and giving rise to more memory B cells and also differentiating into plasma cells	Terminally differentiated cells that constitutively produce antibody. Not stimulated by antigen (low to no surface B cell receptor). Do not divide

a) List of markers commonly used to distinguish between memory B cells and plasma cells in mice and humans (not a comprehensive listing). All of the markers listed here except for Blimp-1 are expressed at the cell surface and can be used to separate plasma cells from memory B cells.

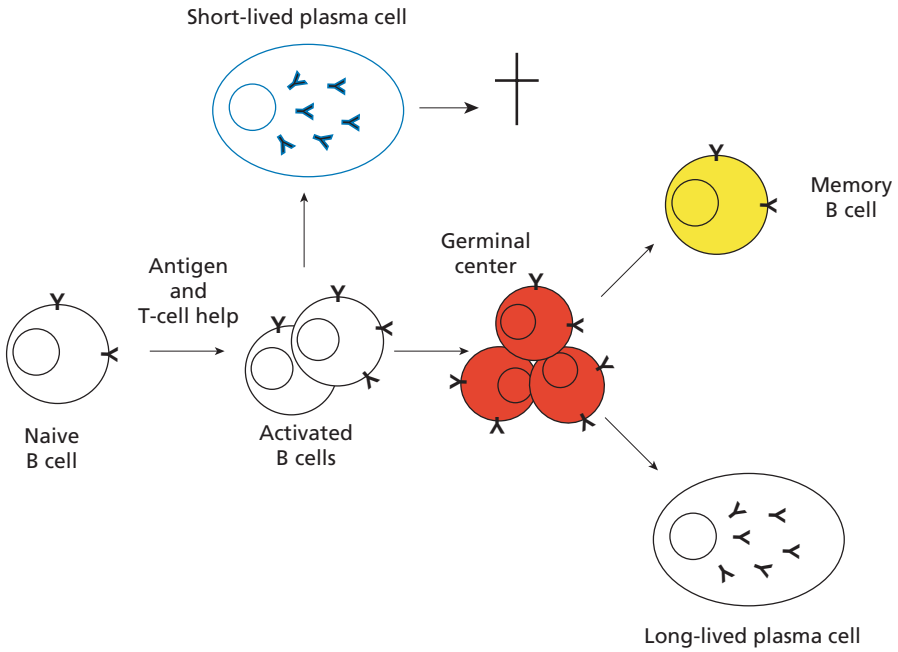

Figure 2 *Model of memory B-cell differentiation. After antigenic stimulation, naive B cells undergo clonal expansion and form clusters of activated B cells known as extrafollicular foci. These activated B cells can either differentiate into short-lived plasma cells or migrate back into the follicle and initiate a germinal center reaction. After proliferation and affinity maturation, germinal center B cells produce both long-lived plasma cells, which in turn produce high-affinity antibodies, and memory B cells which have high-affinity B-cell receptors.*

affinity antibodies that are much more efficient at controlling and eliminating the pathogen (which is done by the antigen-specific B cells that initiate GCs).

The kinetics and anatomical location of antibody production after an acute viral infection in mice are shown in Figure 3. The IgM response is transient but the serum IgG response is long-lived and can persist for several years. Antibody is initially produced by short-lived plasma cells present in the secondary lymphoid organs. The plasma cell response in these tissues peaks during the first 2 weeks and then declines within 2–4 weeks after infection (Slifka et al. 1995). As splenic plasma cell populations decline, antigen-specific plasma cells begin to migrate to and/or accumulate in the bone marrow compartment. After the GC reaction subsides, the bone marrow becomes the predominant site of antibody production, with 80–90 percent of the host's plasma cells located in this compartment (Slifka et al. 1995, 1998).

Upon reinfection, antibody responses occur rapidly in the spleen and lymph nodes, because most of the memory B cells reside in these organs. After secondary infection, the memory B cells in spleen and lymph nodes proliferate and/or differentiate into plasma cells, resulting in a transient increase in the number of antibody-secreting cells (ASC) in the spleen. However, once the secondary infection has cleared, this response subsides and, once again, the bone marrow becomes the predominant site of antibody production. It is worth noting the anatomical segregation between plasma cells and memory B cells. One way of looking at this is to consider the spleen and lymph nodes as 'factories' where

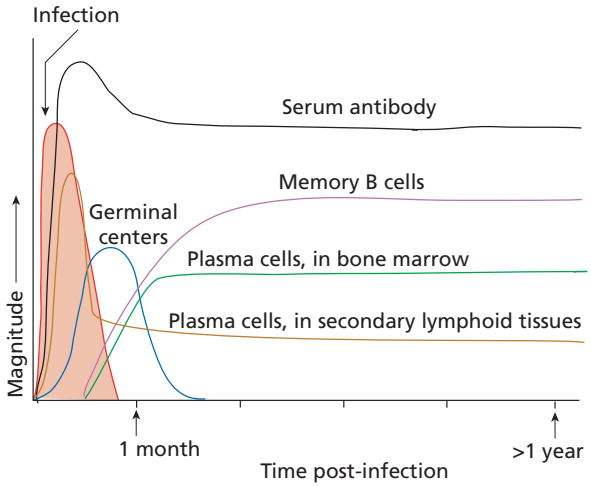

Figure 3 *Kinetics and anatomical site of B-cell responses after infection. Initial antibody production is by short-lived plasma cells in the spleen and lymph nodes. Germinal centers form and are maintained for approximately 2–6 weeks after antigen clearance. Long-lived plasma cells and memory B cells are produced from the germinal centers. Most of the long-lived plasma cells migrate to and reside in the bone marrow, though some stay in secondary lymphoid organs. Long-lived plasma cells in the bone marrow are generally responsible for most of the maintenance of serum antibody levels. Most of the memory B cells reside in secondary lymphoid organs long term, although some migrate to and reside in the bone marrow.*

B-cell differentiation into plasma cells occurs, and the bone marrow as the storehouse where the products (i.e. plasma cells) are kept. It makes sense that memory B cells should reside in the vicinity of the factories so that they can be quickly mobilized into action as the need arises, and that the plasma cells are shipped out to the bone marrow to make room in the factory. Plasma cells residing in the bone marrow go on with their business of making antibody, which ends up in the blood and can protect against reinfection. Note that some plasma cells are expected to reside in mucosal tissues and produce IgG and IgA which is secreted to protect the mucosal surfaces, and it should also be pointed out that serum antibody (IgG) can enter the mucosa by transudation and it is therefore possible that plasma cells residing in the bone marrow also contribute to the antibody present at mucosal sites.

The factors that are critical for generation of B-cell memory and plasma cells can be divided into three groups: (1) genes essential for FDC development, (2) B-cell intrinsic factors, and (3) CD4 T-cell intrinsic factors. TNFR1, LTα, and LTβ are essential for FDC development. CD40, CD19, and AID are examples of critical B-cell intrinsic factors (see Tsiagbe and Thorbecke 1998, for a more extensive list). CD28, B7-1/2, ICOS, and CD40L are examples of CD4 T-cell intrinsic factors required for the generation of GCs and development of B-cell memory (McAdam et al. 2001; Tafuri et al. 2001; Borriello et al. 1997; Xu et al. 1994). Interestingly, the intracellular signaling protein SAP (SLAM-associated protein; also known as SH2D1A), which is defective in individuals with the genetic disease X-linked lymphoproliferative (XLP), is essential in CD4 T cells for the generation of GCs and B-cell memory, but not for most other CD4 T-cell functions (Crotty et al. 2003b).

A separate set of genes has been identified that is specifically required for plasma cell differentiation, and XBP-1 and Blimp-1 are two critical B-cell transcription factors controlling the plasma cell differentiation program (Shaffer et al. 2001, 2002; Zhan et al. 2002). Within GCs, multiple factors play a role in determining the ratio of memory B cell versus plasma cell production, including Bcl-6, interleukin 10 (IL-10), OX40, and others (Tsiagbe and Thorbecke 1998).

In summary, immunological memory in the B-cell compartment consists of memory B cells and plasma cells – two distinct cell types with different anatomical locations and very different functions (Table 5). Memory B cells are located primarily in the secondary lymphoid organs and are present at much higher frequencies than naïve B cells of the same specificity. In addition to this quantitative advantage over naïve B cells, memory B cells are also qualitatively different and produce antibody of much higher affinity. However, memory B cells do not actively secrete antibody (i.e. they are not effector cells). Their major function is to make rapid recall responses to infection by quickly dividing and differentiating into plasma cells, as well as initiating new GCs. The rapid rise in antibody concentration upon reinfection is the result of memory B-cell differentiation into new antibody-secreting plasma cells. In contrast to memory B cells, plasma cells cannot be stimulated by antigen either to divide or to increase their rate of antibody production. These plasma cells are terminally differentiated cells that constitutively produce and secrete antibody. Plasma cells are extraordinarily efficient in their ability to make antibody; it has been estimated that plasma cells can secrete >1000 antibody molecules per second (Helmreich et al. 1961; Hibi and Dosch 1986). As pre-existing antibody provides the first line of defense against infection by microbial pathogens, the importance of plasma cells in protective immunity cannot be overstated. In fact, it could be argued that plasma cells may be the single most important cell type in protective immunity to infections.

T-cell memory

T-cell memory does not have a plasma cell equivalent, i.e. an effector cell that can continue its effector function in the absence of antigenic stimulation. In contrast to plasma cells, effector T cells elaborate their effector functions (i.e. cytokine secretion and killing of infected cells by release of secretory granules containing perforin/granzymes) only in the presence of antigen (see Figure 1 and Table 3). These cells exhibit an on–off lifestyle with antigen regulating this switch (Badovinac et al. 2000; Slifka and Whitton 2000). If effector T-cell responses are only transient, then what is the cellular basis of long-term T-cell immunity? It is well established that T-cell memory, as assessed by accelerated recall responses in vivo, is long-lived and is seen after most microbial infections (Ahmed and Gray 1996; Zinkernagel et al. 1996; Dutton et al. 1998; Freitas and Rocha 2000). These rapid recall responses to reinfection are the result of both quantitative and qualitative changes in the pathogen-specific T cells. On primary infection there is substantial expansion of the pool of both CD8 and CD4 T cells specific to the pathogen (Figure 4). Several studies have shown that the size of the memory T-cell pool is determined by the burst size during the expansion phase (Figure 5) (Hou et al. 1994; Busch et al. 1998; Murali-Krishna et al. 1998; Butz et al. 1998). In the case of some acute viral infections, the increase in the number of antigen-specific T cells can be as great as 1000- to 5000-fold (Murali-Krishna et al. 1998; Ahmed and Biron 1999). This numerical advantage alone can make an enormous difference to the recall response, but recent studies have shown that memory T cells are also qualitatively distinct from naïve T cells and can respond with much quicker cytokine secretion and killing on re-exposure to antigen (Zimmerman et al. 1996; Kedl and Mescher 1998; Bach-

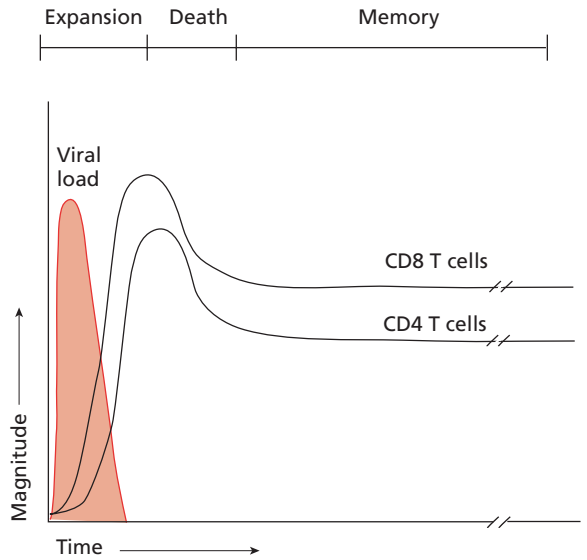

Figure 4 *Antiviral CD8 and CD4 T-cell responses. The three phases of the immune response are indicated at the top. The increase in cell number during the 'expansion' phase is the result of clones of T cells undergoing cell division. Soon after the virus is cleared, there is a 'death' phase characterized by decreasing numbers of virus-specific T cells caused by apoptosis. Following the death phase, the number of virus-specific T cells stabilizes and can be maintained for extended periods. This is the 'memory' phase. The CD4 T-cell response is similar to the CD8 T-cell response except that the magnitude of the CD4 response is usually lower and slightly delayed, and the death phase can be more protracted than the CD8 response.*

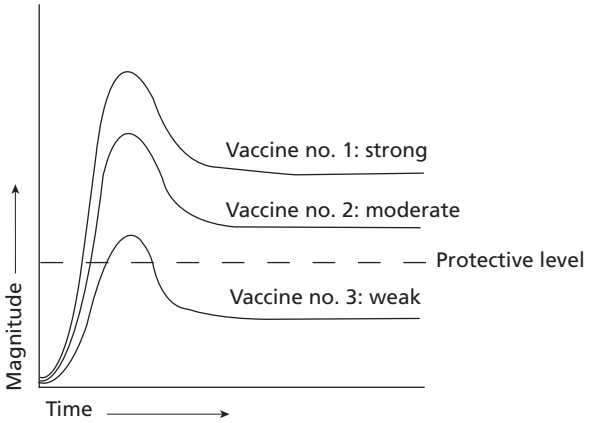

Figure 5 *The size of the memory T-cell pool is determined by the clonal burst size during the expansion phase. In this figure, the lines represent the T-cell responses induced by three different vaccines. Vaccine number 1 induces the largest expansion of T cells and hence generates the largest pool of memory T cells, vaccine no. 2 is next, and vaccine no. 3 is the weakest. The asterisk denotes the minimum number of antigen-specific T cells required for protective immunity. In this scenario, vaccines nos 1 and 2 will confer long-term immunity whereas protective immunity induced by vaccine no. 3 will be of short duration. The main reason for the failure of vaccine no. 3 is a smaller burst size during the expansion phase. Note that the maintenance of the memory T-cell pool is similar for all three vaccines.*

mann et al. 1999a, 1999b; Cho et al. 1999; Barber et al. 2003).

In fact, this faster responsiveness is clearly the defining functional characteristic of memory T cells (Table 6). Another important property of memory T cells is their ability to extravasate into nonlymphoid tissues; several recent studies have shown that a subset of memory T cells (termed 'effector' memory) are present in many peripheral tissues and also at mucosal sites (Sallusto et al. 1999; Masopust et al. 2001; Reinhardt et al. 2001). Thus, it is the combination of increased numbers of antigen-specific T cells, their faster responsiveness, and their better location (i.e. near sites of microbial entry) that underpins T-cell memory, and explains how memory T cells confer long-term protective immunity (Lau et al. 1994; Ahmed and Gray 1996; Zinkernagel et al. 1996; Dutton et al. 1998; Freitas and Rocha 2000).

It is well established that memory B cells and plasma cells differentiate along separate arms of a bifurcated pathway, and some of the conditions and signals that direct naïve B cells into the memory versus effector pathways are being defined (McHeyzer-Williams and Ahmed 1999; Calame 2001; Fearon et al. 2001). Our understanding of the memory T-cell differentiation pathway is less clear, but over the past few years there has been substantial progress in defining the lineage interrelationships of naive, effector, and memory T cells (Champagne et al. 2001; Lanzavecchia and Sallusto 2001; Kaech et al. 2003). Also, several markers have been identified that distinguish these three cell types (Table 7) (Ahmed and Gray 1996; Zinkernagel et al. 1996; Dutton et al. 1998; Freitas and Rocha 2000;

Table 6 *Defining characteristics of memory B and T cells*

Memory B cells
The hallmark of memory B cells is affinity maturation of the B-cell receptor. This means that the antibody produced by these cells (after their differentiation into antibody secreting cells) is of higher affinity. Thus, the fundamental difference between naïve and memory B cells is that the memory B cells can make a better 'product'. It is also likely that memory B cells respond to antigen stimulation more efficiently than naïve B cells
Memory T cells
The hallmark of memory T cells is faster responsiveness on re-encountering the antigen. In some instances the response is so rapid (i.e. cytokine production in less than 4 h) that memory T cells give the illusion of being effector cells. The effector molecules (cytokines, perforin, granzymes, etc.) of naïve and memory T cells are identical. Thus, the fundamental difference between memory and naïve T cells is that the memory T cells are a much more efficient 'factory' than naïve cells, although the product is the same. Also, unlike naïve T cells, which are located mostly in lymphoid tissues, a subset of memory T cells ($CD62^{lo}$ $CCR7^{-}$) is present in nonlymphoid tissues and at mucosal sites and can immediately confront the invading pathogen

Harrington et al. 2000). Possible models of memory T-cell differentiation are shown in Figure 6. It is unlikely that the 'divergent pathway' (model 1 – Figure 6a) represents a major pathway of memory T-cell differentiation because recent experimental evidence favors the linear differentiation model (model 2 – Figure 6b). Studies using transgenic T cells, or genetic techniques to mark antigen-specific T cells, have shown that memory T cells are derived from effector cells (Jacob and Baltimore 1999; Opferman et al. 1999). However, this simple linear differentiation model does not directly account for the fact that most effector cells undergo apoptosis and only a fraction (about 10 percent) of these cells survive to become memory cells. A second approach, using experiments involving adoptive transfer of effector T cells into naïve mice, showed that memory T cells probably arise directly from this population (Opferman et al. 1999; Hu et al. 2001; Kaech et al. 2003).

The 'decreasing potential hypothesis' (model 3 – Figure 6c) incorporates a mechanism for discriminating between effectors that preferentially die and those that preferentially survive and differentiate into memory cells (Kaech et al. 2002). According to this model the balance between effector cells and memory cells is governed by the duration and level of antigenic stimulation. Cells become more and more terminally differentiated with prolonged antigenic stimulation and this is accompanied by an increasing susceptibility to apoptosis and a decreasing potential for memory cell development. This model also explains the phenomenon of clonal deletion/exhaustion that occurs during chronic viral infections with a high antigen load (Moskophidis et al. 1993; Zajac et al. 1998; Ahmed and Biron 1999). Finally, the last memory differentiation model we would like to discuss incorporates the development of 'central' and 'effector' memory T cells (Figure 7) (Sallusto et al. 1999). In this model, a shorter duration of antigenic stimulation favors the development of 'central' memory cells whereas longer duration favors 'effector' memory cells. 'Effector' memory cells ($CCR7^{-}$, $CD62L^{lo}$) are characterized by rapid acquisition of effector function and are found predominantly in nonlymphoid tissues, whereas 'central' memory cells ($CCR7^{+}$, $CD62L^{hi}$) are located within lymphoid tissues and presumably respond slower than 'effector' memory cells. However, it should be noted that even the 'central' memory cells respond much faster than naïve T cells. There are some interesting parallels between the 'decreasing potential' model and the model incorporating the development of 'central' and 'effector' memory T-cell subsets. In both models, the duration of antigenic stimulus regulates differentiation and a more prolonged antigenic stimulus favors cells with a more effector phenotype (i.e. terminally differentiated cell) (Kaech et al. 2002).

MAINTENANCE OF IMMUNOLOGICAL MEMORY

How is immunological memory maintained? This question has fascinated immunologists, microbiologists, and infectious disease specialists for many years, and there has been great interest in understanding the mechanisms that maintain long-term protective immunity. This infor-

Table 7 *Markers that distinguish naıve,¨effector, and memory T cells*[a]

	Naive	Effector	Memory

CD45RO	Low	High	Low/High

a) Not a comprehensive list but illustrates the three patterns of changes seen as naïve T cells go through the naïve→effector→memory transition. Some surface markers (group A) are expressed at low levels in naïve cells, then upregulated upon antigen activation (effector cells) and maintained at high levels in memory T cells. Other markers as shown in group B are only transiently upregulated in effector cells and can be useful in discriminating between memory and effector T cells. Finally, a third group of markers (group C) show a much more gradual change during the effector-to-memory transition and have turned out to be very useful in identifying different subsets of memory T cells, i.e. lymphoid versus nonlymphoid. This group of markers may also be useful in identifying the various stages of memory T-cell differentiation.

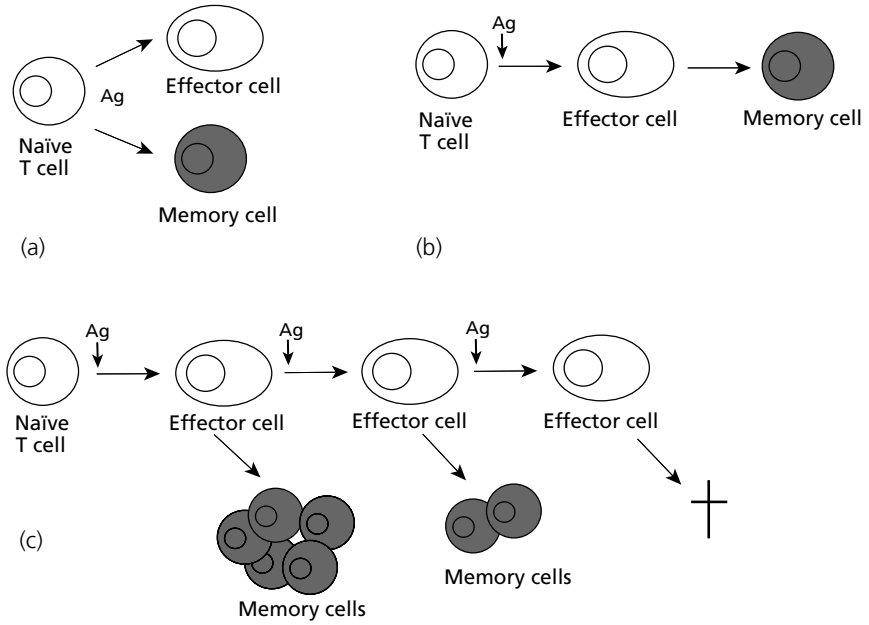

Figure 6 *Models of memory T-cell differentiation.* **(a)** *Model 1 represents the B-cell/germinal center paradigm of dichotomy in memory and effector pathways.* **(b)** *Model 2 is the more traditional view of memory T-cell differentiation representing a linear differentiation pathway.* **(c)** *Model 3 is a variation of model 2 and takes into account the finding that only 5–10 percent of the effector cells survive to become memory T cells. In this model, progress toward terminal differentiation (driven by antigen – Ag) is accompanied by increased susceptibility to apoptosis and a decreased potential for memory cell development. In all of these models the effector cell represents a transient population whereas the memory cells survive for long periods. On re-exposure to antigen, the memory T cells can develop into effector cells and also generate more memory cells.*

mation is important for a fundamental understanding of both immunological memory and vaccine development.

The mechanisms involved in sustaining immunological memory are listed in Table 8. These can be divided into two categories: antigen dependent and antigen independent. One of the most effective means of maintaining immunity is periodic re-exposure to the pathogen. Such reinfections are usually asymptomatic or produce only mild clinical symptoms and serve as a natural 'booster' to the immune system. The importance of this mechanism is documented by epidemiological studies which show that protective immunity is maintained for longer periods in individuals living in areas endemic for a given disease. Having said this, it is equally, if not more, important to point out that there are several striking examples of long-term protective immunity in the absence of re-exposure to the pathogen. Three such examples are given in Table 9. These observations were crucial in shaping our ideas about immunological memory because they showed that the immune system could remember an encounter that occurred many years before and that there are mechanisms for sustaining this long-term memory (Panum 1847; Paul et al. 1951; Sawyer 1931).

Among the 'not reinfection' mechanisms of maintaining immunity, two are antigen dependent: microbial

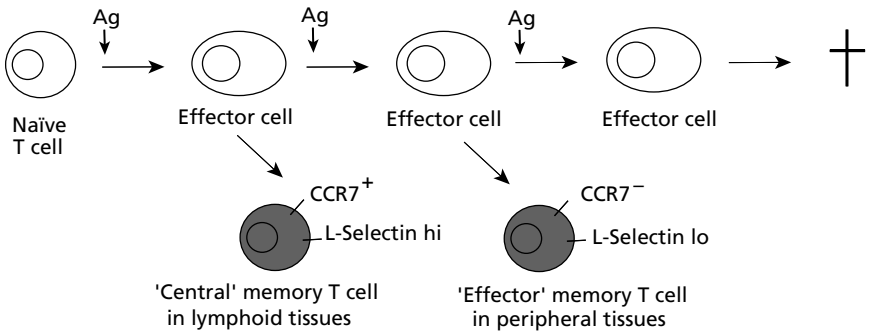

Figure 7 *Model of memory T-cell differentiation incorporating the development of 'central' and 'effector' memory T cells. In this model a short duration of antigenic stimulation favors the development of 'central' memory cells whereas longer duration favors differentiation to 'effector' memory T cells. Ag, antigen.*

Table 8 *Maintenance of immunological memory*

Antigen-dependent
1. Re-exposure to pathogen can serve as a periodic natural booster to the immune system
2. Low grade chronic/latent infection. Many pathogens can persist at low levels and provide a continuous/intermittent stimulus to memory T and B cells
3. Antigen–antibody complexes on follicular dendritic cells can persist for extended periods and provide a reservoir of antigen that possibly stimulates memory B cells and CD4 T cells
Antigen-independent
1. Long-lived plasma cells can constitutively produce antibody, sustaining serum antibody levels in the absence of antigen
2. Memory B and T cells can persist and maintain their numbers in an antigen-free environment. Memory T cells can undergo homeostatic proliferation to replenish their pool; this homeostatic proliferation does not require stimulation with antigen
3. Memory CD8 and CD4 T cells can retain their rapid responsiveness in the absence of antigen and are able to confer protective immunity

There are antigen-dependent and antigen-independent mechanisms of maintaining long-term immunity to infection.

persistence and antigen depots. A number of microbes can persist at low levels in healthy individuals and this chronicity can provide either a continuous or an intermittent antigenic stimulus to the immune system. This can be an effective mechanism of maintaining a higher frequency of antigen-specific T and B cells but requires a careful balance between pathogen levels and immune responses. This critical balance is necessary to avoid excessive immunopathology and also to avoid overstimulation of the antigen-specific T cells to such an extent that these cells get deleted or functionally exhausted (Moskophidis et al. 1993; Zajac et al. 1998). Pathogens that cause latent infection with periodic reactivation, such as the herpesviruses (Epstein–Barr virus (EBV), herpes simplex virus (HSV), varicella-zoster virus (VZV)) exhibit a lifestyle that is perhaps most conducive to providing an antigenic stimulus for maintaining long-term immunity.

The second antigen-dependent mechanism, antigen depots, relies on the ability of FDCs to trap antigen–antibody complexes on their cell surface and retain them for extended periods of time (Mandel et al. 1980; MacLennan 1994; Bachmann et al. 1996; Zinkernagel et al. 1996; Dutton et al. 1998; Ahmed and Biron 1999; Freitas and Rocha 2000). FDCs express Fc receptors on their cell surface and antigen–antibody complexes can bind to these Fc receptors. It appears that FDCs do not internalize these antigen–antibody complexes but instead display them on their cell surface for long periods, thus promoting maintenance of GCs and continued affinity maturation of B cells. It is generally agreed that antigen is required to maintain GC reactions, to sustain the rapid B-cell proliferation, provide a substrate for positive selection, and prevent apoptosis (MacLennan 1994). Some studies have suggested that antigen can persist on FDCs for more than a year (Mandel et al. 1980). Data from the only study directly tracking antigen in GCs after a viral infection suggest that GCs are sustained by antigen on FDCs for about 30 days after clearance of the virus, after which there is a greater than 90 percent drop in the number of GCs and a greater than 90 percent drop in the amount of viral antigen bound by the FDCs (Bachmann et al. 1996).

It is unlikely that viral particles or protein antigens in vivo can survive the wear and tear of antibody binding for long before being broken into pieces or destroyed. It has been postulated that this trapped antigen directly stimulates the specific B cells and can also be acquired by the B cells, processed and then presented via MHC class II molecules to CD4 T cells (Mandel et al. 1980; MacLennan 1994). Thus, it appears that FDC-trapped antigen can be used for stimulating both memory B cells and CD4 T cells. Many interesting questions about FDCs remain unanswered. What is their half-life? Do these cells divide? What prevents the antigen–antibody complexes from being degraded and/or internalized by the FDCs? What is the half-life of antigen presented by an FDC? It will be important to study FDCs in more detail for better understanding of their role in maintaining B- and T-cell memory.

During the past decade major advances have been made in identifying antigen-independent mechanisms of maintaining immunological memory (Ahmed and Gray 1996; Dutton et al. 1998; Freitas and Rocha 2000; Marrack et al. 2000; Lanzavecchia and Sallusto 2001; Sprent and Surh 2001). These studies were greatly facilitated by the development of new and sensitive techni-

Table 9 *Long-term immunity in the absence of re-exposure to the pathogen*

Infection	Duration of immunity (years)	Reference
Measles on the Faroe Islands	65	Panum (1847)
Yellow fever virus in Norfolk, VA, USA	75	Sawyer (1931)

ques for assessing T- and B-cell functions at the single cell level and, even more importantly, by the ability physically to identify antigen-specific T cells using MHC class I and class II tetramers (Altman et al. 1996; Crawford et al. 1998; Murali-Krishna et al. 1998; Butz and Bevan 1998). Also, the use of transgenic T and B cells in mouse model systems has allowed us to monitor the immune response in vivo as naïve cells get activated and differentiate into effector and memory cells (Kearney et al. 1994; Zimmermann et al. 1999). Using a combination of these approaches to analyze a variety of immune responses in mice (using both infectious and noninfectious model systems), it is now clear that both memory CD4 and CD8 T cells, as well as memory B cells, can persist in the absence of antigen (Hou et al. 1994; Lau et al. 1994; Mullbacher 1994; Ahmed and Gray 1996; Tanchot et al. 1997; Dutton et al. 1998; Markiewicz et al. 1998; Murali-Krishna et al. 1999; Swain et al. 1999; Freitas and Rocha 2000; Marrack et al. 2000; Maruyama et al. 2000; Lanzavecchia and Sallusto 2001; Sprent and Surh 2001). It has also been shown that memory T cells can undergo homeostatic proliferation to replenish their numbers and that this proliferative renewal does not require stimulation with antigen (Tanchot et al. 1997; Murali-Krishna et al. 1999; Swain et al. 1999; Sprent and Surh 2001; Kassiotis et al. 2002). Taken together, these experimental studies done in mice have unequivocally shown that memory B and T cells can persist for extended periods (2 years or more) in the absence of antigen.

What about the situation in humans? Here the results are less definitive, but there are data showing long-term memory under conditions where antigen persistence is unlikely, e.g. it has been shown that vaccinia virus-specific memory CD8 T cells can be detected in individuals immunized more than 30 years earlier (Demkowicz et al. 1996; Crotty et al. 2003a; Hammarlund et al. 2003). It is unlikely that this long-term CTL memory is the result of antigenic stimulation, because vaccinia virus does not cause a chronic or latent infection in humans and there is no possibility of re-exposure to vaccinia virus, because vaccination against smallpox virus was discontinued in 1977. There are also studies documenting persistence of memory CD4 T cells to tetanus toxoid many years after immunization (Helms et al. 2000). There is also data showing that memory B cells persist for greater than 50 years after smallpox vaccination (Crotty et al. 2003a). Nevertheless, there is clearly a need for more detailed analysis of memory responses in humans. It would also be worthwhile to pursue such studies in nonhuman primates.

What factors control antigen-independent maintenance of memory B and T cells? The answer to this question is unclear for memory B cells, but this issue of homeostatic maintenance of memory has received a great deal of interest in the study of memory T cells, and it is now clear that cytokines (such as IL-15 and IL-7) play a major role in controlling homeostatic proliferation (Sprent and Surh 2001; Becker et al. 2002; Goldrath et al. 2002; Kaech et al. 2002; Kieper et al. 2002; Tan et al. 2002).

It is clear that there are antigen-independent mechanisms for maintaining memory B and T cells, but what about antibody production? The traditional view has been that plasma cells are short-lived cells (half-life estimates ranging from 3 days to at most 2–3 weeks), and that continuous antigenic stimulation of memory B cells is essential to replenish the pool of rapidly dying plasma cells and thereby maintain antibody production. This view has been challenged by recent studies showing that plasma cells can live for extended periods and that some plasma cells can survive for the life of the mouse (Manz et al. 1997, 1998; Slifka et al. 1998; Helms et al. 2000). This finding may provide an explanation for the remarkable longevity of antibody responses seen in humans after certain acute infections and immunizations (Ahmed and Gray 1996; Slifka and Ahmed 1998). Many acute viral infections induce serum antibody responses that persist for decades (Plotkin and Orenstein 1999), but what is even more striking is that some nonreplicating antigens can also induce long-term humoral immunity. Perhaps the most impressive demonstration of this phenomenon is the large study of poliovirus immunity done in Sweden (Bottiger et al. 1998). The Swedish population is almost ideal for such a study, for several reasons: (1) poliomyelitis has been eliminated in Sweden since 1962; (2) only inactivated poliovirus vaccine (IPV) (the Salk vaccine) has ever been used in the Swedish population; (3) the vaccine is provided by a single, standardized supplier; (4) the final booster immunization is given at the young age of 5 years; (5) the enterovirus infection burden in Sweden is extremely low, and there are relatively few opportunities for introduction of poliovirus from foreign sources; and (6) Sweden has excellent healthcare records and public health surveillance. Given these factors, it is striking to see that, when the Swedish population was surveyed for poliovirus immunity in 1991, substantial antipoliovirus antibody titers were detected in all age groups (Bottiger et al. 1998). Interestingly, there was virtually no difference in serum antibody titers among the different age groups (all at >10 years after immunization), indicating that antipoliovirus antibody titers are stably maintained in the absence of additional immunizations or exposure to live virus (Bottiger et al. 1998). In addition, it is well described that people immunized with diphtheria or tetanus toxoid can have circulating antibody for more than 25, or even 50, years (Scheibel et al. 1966; Simonsen et al. 1984; Kjeldsen et al. 1985; Cohen et al. 1994; Bottiger et al. 1998).

CONCLUSION

Not all infections and vaccines induce long-term antibody responses and there are several instances where antibody responses decay rapidly (Plotkin and Orenstein

1999). The underlying reasons for this are not well understood. Are there only certain conditions and/or antigen formulations that can result in the generation of long-lived plasma cells? One possibility is that T-cell help is necessary and that only high-affinity B cells can differentiate into long-lived plasma cells, whereas low-affinity B cells give rise to short-lived plasma cells. What are the factors that regulate plasma cell survival? Is residence in the bone marrow essential for plasma cell survival? These issues about plasma cells need to be addressed to gain a better understanding of long-term humoral immunity.

In conclusion, in this chapter we have attempted to give an overview of the principles of immunological memory to infection. This remains one of the most exciting areas of immunology and infectious diseases and there are many challenges ahead. Although considerable progress has been made in the past few years, and some of our questions have been answered, many more remain, e.g. what is the molecular definition of a memory T cell? Are there memory specific genes? How are these cells 'wired', making them so different from naïve cells (Bachmann et al. 1999b)? What controls the homeostasis of memory T and B cells? How many memory cells can we accommodate as we age and encounter multiple infections (Selin et al. 1999)? What signals regulate the differentiation program of memory cells (Kaech and Ahmed 2001; Lanzavecchia and Sallusto 2001; van Stipdonk et al. 2001; Wong and Pamer 2001)? Answers to these and many other questions are needed to define the cellular and molecular basis of immunological memory.

THE CONCEPT OF RECIRCULATION: LYMPHOCYTES VERSUS LEUKOCYTES

The immune system protects the body from invading microorganisms and parasites and surveys the tissues for expression of aberrant selfantigens. The principal players in this defense system are the leukocytes, and they are well equipped to cope with virtually any pathogen. However, most pathogens have the advantage of an extremely high proliferation rate, and prevention of systemic infections and damage requires appropriate rapid responses from innate and adaptive immune systems. Although all the cells of the innate immune system are able to mount fast responses against various antigens, the response of the adaptive, specific branch is greatly hampered by the low number of cells specific for a given antigen. To counterbalance this disadvantage, cells of the adaptive immune system, i.e. lymphocytes, follow distinct migration and recirculation routes in order to maximize a possible encounter with their cognate antigens and to be strategically positioned at sites of antigen entry.

Cells of the innate immune system are the first effector cells that arrive at the site of infection or tissue damage. As they constitute a uniform antigen nonspecific pool, they can be rapidly recruited in large numbers and, having exerted their function, they are deleted. The recirculation of lymphoid cells contrasts markedly to the unidirectional migration of cells of the innate immune system from blood into tissue. Lymphocytes have a complex migration pattern that is strongly dependent on their state of activation and memory. They have the ability to recirculate, i.e. to re-enter the systemic blood circulation from tissues and migrate to a distant site in the body (Figure 1). The reason for this recirculation behavior is presumably the relatively low number of antigen-specific lymphocytes that can be generated for each of the millions of antigens. Positive and negative selections of antigen receptors produce a vast number of specificities, but necessarily only a very small number of cells for any given specificity. Therefore, the migration of lymphocytes is highly organized to ensure an efficient exposure of lymphocytes to their cognate antigens in secondary lymphoid organs. Moreover, clones with relevant specificities, i.e. receptors that recognize antigenic epitopes of foreign organisms, are not lost after their engagement, but are preserved as memory cells for more rapid and stronger responses on reinfection with the same organism. This generation of memory within the specific immune system is the rationale for immunization and it can persist and protect an organism for the rest of its life. Thus, the constitutive recirculation of lymphocytes through secondary lymphoid tissues is distinct from the leukocyte recruitment occurring at sites of inflammation where vascularized tissues respond to damages.

MIGRATION OF LYMPHOCYTES

The initial experiments to study the origin of cells in the lymph (hence the name lymphocytes) were conducted

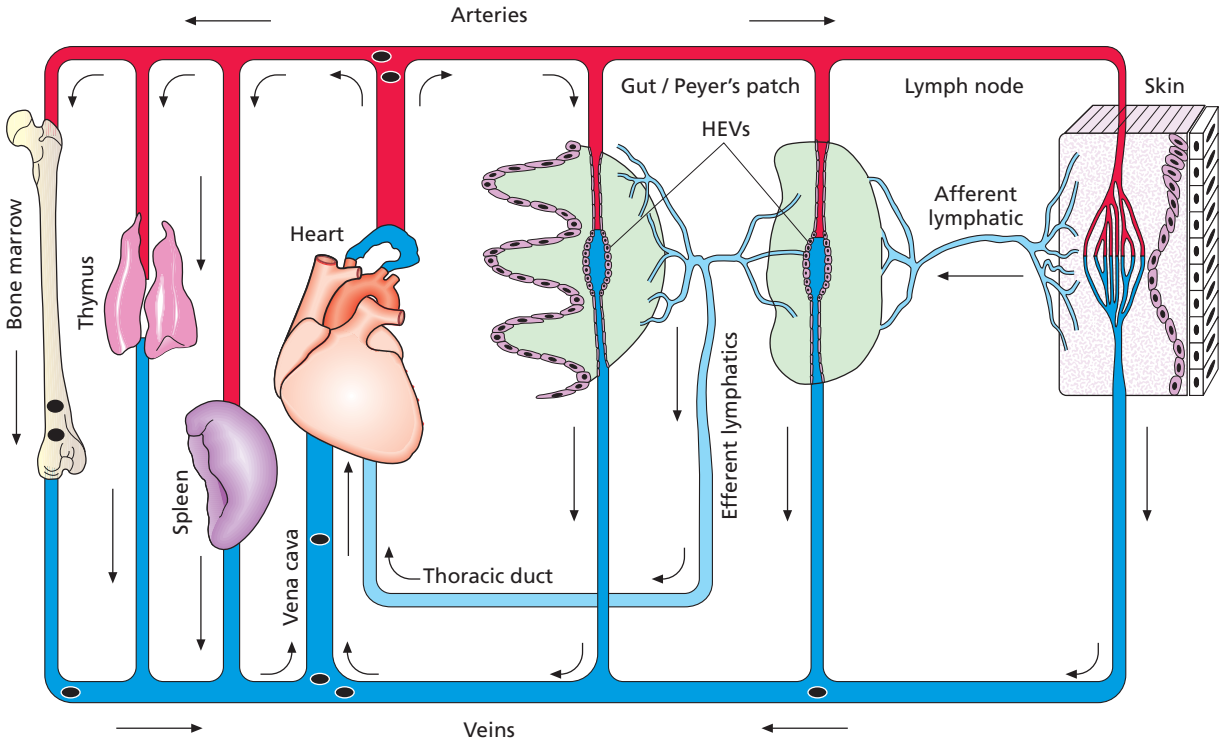

Figure 1 *Routes of lymphocyte migration and recirculation. The diagram depicts blood and lymphatic connections between primary and secondary lymphoid organs. The naïve lymphoid cells are located in the thymus (T cells) or bone marrow (B cells) and reach the secondary lymphoid organs as indicated. Lymphoid cells circulating through the blood system enter in organs through postcapillaries venules (skin) or high endothelial venules (HEVs) in Peyer's patches and lymph nodes. The second system used by lymphocytes is the lymphatic system (in black), which drains immune cells from peripheral tissues through lymph nodes and mucosa-associated tissues (MALT) back to the blood via the thoracic duct.*

by James Gowans and colleagues (Gowans 1957; Gowans and Knight 1964). They were the first to show that cells in the lymphatics are blood-borne cells that have the ability to circulate between blood and lymph in order to seek out their cognate antigen, constituting the so-called immune surveillance (Pabst and Binns 1989; Salmi and Jalkanen 1997). Westermann and Pabst have estimated that, in humans, about 5×10^{11} lymphocytes leave the blood each day to enter various organs and then return to the blood (Westermann and Pabst 1990, 1996). In lymphoid organs, lymphocyte extravasation occurs in the postcapillary venules (Gowans and Knight 1964) at specialized postcapillary vascular sites called high endothelial venules (HEV) (Anderson and Anderson 1976; Anderson et al. 1976). These represent the major constitutive extravasation route in vivo (Lasky 1992), and most recirculating lymphocytes selectively bind to the endothelium of HEVs, while ignoring normal vascular endothelium (Mackay et al. 1990). In humans, HEVs are found in all secondary lymphoid organs except the spleen. Endothelial cells of HEVs have a cuboidal appearance that differs considerably from the flat morphology of other endothelial cells (Girard and Springer 1995). In addition to this characteristic morphology, endothelial cells of HEVs differ from others by the specific expression of several genes increasing their adhesive properties for lymphocytes (Girard et al. 1999). Consequently, leukocytes are more likely to collide with, adhere to, and migrate across endothelial cells of HEVs than any other nonstimulated resting endothelial cells (Bjerknes et al. 1986; Johnson-Leger et al. 2000). This constitutive specialization of HEVs to sustain leukocyte recirculation contrasts sharply with the situation at inflamed sites, where the damaged tissue triggers new adhesive properties in the adjacent endothelium in order to induce directional migration of lymphocytes toward the site where the immune effector function takes place (Muller 2002).

STRUCTURE AND ORGANIZATION OF LYMPHOID TISSUES

Lymphoid structures are divided into primary and secondary lymphoid organs. The primary lymphoid organs are the thymus and the bone marrow in mammals, which constitute the respective sites of differentiation for T and B cells. Their function is to sustain the lymphoid differentiation toward the stage of acquisition of immunocompetence, e.g. expression of functional antigen-specific receptors on the surface of lymphoid cells. Such cells are named naïve. Precursor lymphoid cells, also termed 'stem cells', are located in the bone

marrow and differentiate in B cells or T-precursor cells, before leaving this organ and seeding secondary lymphoid organs in the case of B cells or thymus in the case of T-precursor cells. Although the migration of T-precursor cells to the thymus is essential for T-cell differentiation, studies of the molecular mechanisms of homing have been hampered by the minute number of precursor T cells leaving the bone marrow and seeding the thymus. Once naïve cells have completed their differentiation in primary lymphoid organs, they specifically migrate to secondary lymphoid organs.

The secondary lymphoid organs encompass the spleen, peripheral and mesenteric lymph nodes, mucosa-associated lymphoid tissue (MALT) including tonsils, and gut-associated lymphoid tissue (GALT) such as Peyer's patches and the appendix. Functionally, the lymphoid organs can be classified into three distinct groups: MALT traps antigens that enter the body through various mucous membrane surfaces, peripheral lymph nodes (PLN) collect antigen from the intercellular tissue fluids, whereas the spleen filters blood-borne antigens (see Figure 1). Although important morphological differences exist among the different secondary lymphoid organs, they all have the common function of concentrating B, T and antigen-presenting cells at unique sites in order to mount efficient immune responses. This is reflected by the presence of discrete structures named lymphoid follicles that can be distinguished histologically in all secondary lymphoid organs. They are especially abundant in mucosal surfaces and consist of aggregates of various lymphoid cells surrounded by a network of draining lymphatic capillaries. These structures are surrounded by a fibrous capsule and contain distinct regions of B- and T-cell activity. Lymph nodes are the most complex secondary lymphoid organs, organized in distinct microenvironments for antigen presentation and lymphocyte recirculation. Afferent lymphatic vessels collect the lymph, antigen-presenting cells (dendritic cells), and lymphocytes from tissue and drain them to peripheral lymph nodes or to intestinal/mesenteric lymph nodes. At the same time, blood-borne lymphocytes enter these lymph nodes via specialized postcapillary venules, the HEVs, in order to encounter the resident cells as well as the cells entering via the afferent lymph. The lymph nodes thus constitute a point where the pathways for antigens and specific effector cells converge. Efferent lymphatic vessels drain the nodes and carry lymph and lymphocytes via the thoracic duct back to the systemic blood circulation into the subclavian vein.

The spleen is adapted to respond to systemic infections by filtering the blood and trapping blood-borne antigens. In contrast to all the other secondary lymphoid organs, the spleen is not connected to the lymphatics and therefore does not directly communicate with the tissues. Furthermore, the spleen lacks HEVs: circulating cells and antigens have unhampered access to this organ through arterioles that terminate open-ended in the sinuses of the marginal zone and through the lack of HEVs. As a result of the high blood flow, the spleen has by far the highest lymphocyte throughput of all lymphoid organs and thus is the organ that lymphocytes pass most frequently.

MOLECULAR MECHANISMS OF LYMPHOCYTE MIGRATION

The multistep paradigm

In the early 1990s, Eugene Butcher and Tim Springer (Butcher 1991; Springer 1994) proposed a multistep paradigm for leukocyte recruitment governed by a different class of adhesion molecules. Although specific molecular interactions have been demonstrated for subsets of leukocytes, and resting and inflammatory situations, leukocyte recruitment always occurs in four different steps, namely: tethering and rolling, triggering, firm adhesion, and transmigration (Butcher 1992). The four different steps involve different classes of adhesion molecules with specific properties. Although additional adhesion molecules have been involved in the initial step, leukocyte rolling is mainly mediated by weak interaction of selectins with their carbohydrate ligands on opposing cells. The rolling is a reversible step but is a prerequisite to the following triggering step by chemokines, leading to leukocyte integrin activation and firm adhesion. This is followed by the final transmigration step, also called diapedesis, which consists of ameboid movement of leukocytes between tightly apposed endothelial cells. This final step involves an active remodeling of interendothelial junctions and has recently received new insights with the discovery of proteins specifically involved in transmigration (Vestweber 2002). Although the models for constitutive and inflammatory lymphocyte recruitment are similar, different adhesion molecules are specifically expressed at sites of constitutive lymphocyte recirculation (HEV) or at sites of inflammatory-induced lymphocyte recruitment (Dailey 1998; von Andrian and Mackay 2000). The specific migration route taken by lymphocytes is controlled by the combined vascular expression of L-selectin ligands, E- and P-selectins, chemokines, integrin ligands, and interendothelial junctional molecules. Mirroring this endothelial diversification, lymphocyte subpopulations express themselves as specific sets of selectin, selectin ligands, chemokine receptors, integrins, and integrin ligands.

Tethering/rolling

The initial rolling step of lymphocytes along the vessel wall is known to depend mainly on weak interactions between selectins and their ligands. Three selectins,

named respectively L-, E-, and P- selectins for leukocytic, endothelial, and platelet selectins, have been identified (Vestweber and Blanks 1999). They all interact with carbohydrate structures and are involved in the regulation of both naive and effector/memory lymphocyte migration. As a result of their anchorage to the actin cytoskeleton, they initiate the adhesion cascade by slowing down the leukocyte along the vascular bed (Dwir et al. 2001) in order to allow the triggering and firm adhesion to occur. In addition, the engagement of selectins leads to signal transduction inside the rolling cells, which may participate in integrin activation (Sikorski et al. 1996; Simon et al. 2000). In contrast to the specific involvement of selectins in lymphocyte rolling, the integrin $\alpha_4\beta_7$ can contribute either to lymphocyte rolling or to firm adhesion (Holzmann et al. 1989; Berlin et al. 1993).

Tethering/rolling of naive lymphocytes

L-selectin is constitutively expressed on virtually all naïve lymphocytes, a portion of memory T cells, neutrophils, eosinophils, and monocytes (Lewinsohn et al. 1987), and is responsible for trafficking of naïve lymphocytes through lymph nodes (Berg et al. 1989). More precisely, L-selectin is implicated in the rolling of naïve lymphocytes along HEVs as demonstrated by real-time intravital video microscopy studies in animals treated with antibody against L-selectin (von Andrian 1996). This C-type lectin interacts with sialyl-Lewis^x structures (sLe^x) found on peripheral lymph node addressins (PNAd) expressed on HEVs such as GlyCAM-1, CD34, podocalyxin, Sgp200, and MAdCAM-1. The optimal binding of L-selectin to its ligands requires sialylation, fucosylation, and carbohydrate sulfation of these ligands by enzymes expressed in HEVs, as demonstrated by the reduced lymphocyte homing to lymph nodes observed in animals deficient for α(1,3)-fucosyltransferase (FucTVII) or *N*-acetyl glycosamine-6-sulfotransferase (HEC-GlcNAc6ST) (Maly et al. 1996; Hemmerich et al. 2001). It is therefore important to consider that optimal L-selectin activity requires expression of PNAd core proteins and post-translational modifying enzymes. Although interaction of L-selectin with its ligands accounts for most lymphocyte entry in lymph nodes, the homing to the mucosal associated tissue in the gut (gut-associated lymphoid tissue or GALT), especially to the Peyer's patches, is only moderately affected in animals deficient for L-selectin, fucosyl, or sulfotransferases (Arbones et al. 1994; Maly et al. 1996; Hemmerich et al. 2001). This is the result of the binding of $\alpha_4\beta_7$ integrin to MAdCAM-1 and to the expression of MAdCAM-1 by HEVs of Peyer's patches (Berlin et al. 1993). Indeed, mesenteric lymph nodes present the features of Peyer's patches and peripheral lymph nodes because they express only MAdCAM-1 on some HEVs, whereas others express MadCAM and L-selectin (Streeter et al. 1988a, 1988b; Berg et al. 1993). However, one could keep in mind that integrin $\alpha_4\beta_7$ represents one of the rare exceptions in which an integrin is used by lymphocytes for rolling.

The significance of integrin $\alpha_4\beta_7$ in lymphocyte homing is best shown in mice that are deficient in the integrin β_7 subunit. The GALT in these mice is severely impaired as a result of the failure of lymphocytes to migrate into the lamina propria, Peyer's patches, and the intraepithelial lymphocyte (IEL) compartment (Wagner et al. 1996). This lymphocyte's homing deficiency is not caused by a defect on HEVs, because naïve β_7-deficient lymphocytes transferred into normal mice normally home to peripheral and mesenteric lymph nodes via L-selectin, but fail to migrate to mucosal effector sites of the gut, i.e. Peyer's patches, lamina propria, and the IEL compartment (Lefrancois et al. 1999).

Tethering/rolling of antigen-primed lymphocytes

Once a naïve lymphocyte encounters its cognate antigen in lymphoid organs, it activates and undergoes dramatic changes in the expression of surface adhesion molecules as it differentiates into an effector or memory lymphocyte (Jung et al. 1988; Picker et al. 1990b; Williams and Butcher 1997). Although subtle differences in expression of adhesion molecules can be found between different effector/memory cell subpopulations (Sallusto et al. 1999; Campbell et al. 2001), the loss of L-selectin expression and the upregulation of ligands for E- and P-selectin by antigen-experienced cells prevent their entry into lymphoid organs (Rigby and Dailey 2000; Hafezi-Moghadam et al. 2001). Notably, this dogma has been recently revised with the identification of memory cell subpopulations that express high levels of L-selectin, migrate toward lymphoid organs, and are called central memory cells (Sallusto et al. 1999; Campbell et al. 2001). Upon leukocyte activation, the downregulation of L-selectin involves transcriptional regulation and protein shedding by surface metalloproteases (Kishimoto et al. 1989; Preece et al. 1996). According to these changes, tethering and rolling of lymphocytes in inflammatory conditions mainly involve P- and E-selectins induced on vascular endothelium by inflammatory stimuli. P-selectin was originally identified in α granules of platelets and later found to be expressed in Weibel–Palade bodies of endothelial cells (Hsu-Lin et al. 1984; McEver et al. 1989). On appropriate stimulation with inflammatory factors such as histamine or thrombin, degranulation of these compartments leads to the rapid expression of P-selectin on the vascular cell surface (Hattori et al. 1989) making it available for interacting with the ligand P-selectin glycoprotein ligand-1 (PSGL-1) or CD24 (the old name was heat stable antigen or HSA) expressed on

the surface of effector lymphocyte subpopulations (Aigner et al. 1995; Borges et al. 1997). Although P-selectin is expressed within minutes of stimulation on the cell surface, E-selectin expression on endothelial cells is transcriptionally regulated by inflammatory cytokines such as tumor necrosis factor α (TNF-α), interleukin 1 (IL-1), or lipopolysaccharide (LPS), leading to expression within 4–24 h (Bevilacqua et al. 1987). Once expressed on the cell surface, E-selectin interacts with ligands expressed on leukocytes, namely E-selectin ligand-1 (ESL-1), PSGL-1, or L-selectin (Vestweber and Blanks 1999). Therefore one important aspect of lymphocyte migration toward the site of inflammation is the expression of E- and P-selectin ligands, among which PSGL-1 is the best characterized. Similar to the binding of L-selectin to the sugar moiety of PNAds, the binding of E-selectins to PSGL-1 requires carbohydrate modifications whereas P-selectin binding requires additional tyrosine sulfations (Pouyani and Seed 1995).

The physiological importance of post-translational modifications of PSGL-1 on lymphocytes is best demonstrated by the functional characterization of an inducible carbohydrate epitope expressed on PSGL-1 and named cutaneous lymphocyte-associated antigen (CLA) (Picker et al. 1990a; Berg et al. 1991). Expression of CLA on T-memory lymphocytes has been found to correlate with the ability of these cells to home to inflamed skin. CLA is a carbohydrate epitope attached to PSGL-1 by fucosyltransferase VII (Fuhlbrigge et al. 1997). The CLA-epitope mediates cell binding to E-selectin expressed on endothelial cells in inflamed skin (Picker et al. 1991) and thereby the recruitment of memory T cells. Differential regulation of CLA seems to occur during the activation of naïve T lymphocytes in peripheral lymph nodes (Borowitz et al. 1993; Picker et al. 1993). Following these initial findings, several studies have shown that the expression of L-selectin and E- and P-selectin ligands, in combination with chemokine receptor expression, can be used to subdivide the different effector and memory lymphocytes subsets upon antigenic challenge (Tietz et al. 1998; Sallusto et al. 1999; Campbell et al. 2001).

This contrasts with integrin β_7 expression which appears sufficient to sustain the migration of lymphocytes to the GALT upon antigenic activation (Rott et al. 1997, 2000; Williams and Butcher 1997; Rose et al. 1998). The unique migration pattern of $\alpha_4\beta_7$-expressing cells is confirmed by the fact that orally administrated antigens result in a higher incidence of antigen-specific cells expressing $\alpha_4\beta_7$ compared with systemic antigen exposure which generates antigen-specific cells within the L-selectin expressing compartment (Lakew et al. 1995; Kantele et al. 1997).

Although this is beyond the scope of this chapter, the reader should be aware that additional adhesion molecules have been implicated in the initial rolling step of lymphocytes (Table 1). This has been demonstrated by using blocking reagents for L-selectin function and the discovery of alternate molecular pathways using CD44, VAP-1, or α_4 integrins (Stoolman 1989; Picker et al. 1989; Alon et al. 1995; Salmi et al. 1997). Although $\alpha_4\beta_1$, CD44, and VAP-1 are all involved in adhesion of lymphocytes on inflammatory endothelium (Elices et al. 1990; Salmi et al. 1993; Maiti et al. 1998), their relative contributions to constitutive versus antigen-primed lymphocyte rolling remain to be formally established in vivo.

FIRM ADHESION: INTEGRINS GUIDE TO THE 'NO RETURN POINT'

In contrast to the rolling step supported by several classes of adhesion molecules, the subsequent lymphocyte arrest is almost exclusively mediated by activated integrin receptors (see Table 1). They constitute the most versatile adhesion molecules because their adhesive properties are regulated with the state of cell activation and because of the nature of activation signals to which leukocytes are exposed (Alon and Feigelson 2002). Integrins are formed of an α and a β subunit, and activation signals change their shape leading to increased affinity of integrins for their ligands (Shimaoka et al. 2002). This is known as a mechanism of inside-out signaling. At the same time, ligand engagement by integrins leads to signal transduction inside the cells in a process called outside-in signaling. Integrin activation occurs within fractions of seconds on chemokine triggering or ligand engagement, implying that most of the circulating lymphocytes express integrins in a nonactivated, resting state. Therefore, leukocyte integrins are exclusively triggered if the rolling step has occurred and if chemokines and endothelial ligands are locally expressed at the site of lymphocyte extravasation.

Among the different heterodimers, $\alpha_L\beta_2$ (LFA-1, CD11a/CD18), $\alpha_4\beta_1$ (VLA-4), and $\alpha_4\beta_7$ (LPAM-1) integrins are the key molecules that mediate firm adhesion of rolling lymphocytes by engagement with their counterreceptors, which include members of the immunoglobulin superfamily (IgSf) (Staunton et al. 1988). The latter can be tentatively classified into two groups: IgSf molecules that are constitutively expressed by endothelial cells at specific sites, such as MAdCAM-1 or intercellular adhesion molecule 2 (ICAM-2) (Staunton et al. 1989; Briskin et al. 1993), and those that are induced by inflammatory stimuli on endothelial cells such as vascular cell adhesion molecule 1 (VCAM-1) or intercellular adhesion molecule 1 (ICAM-1) (Marlin and Springer 1987; Elices et al. 1990). However, it has become clear that this classification is not absolute because constitutive expression of ICAM-1 and VCAM-1 on HEVs has been reported (Tamatani et al. 1991; Sasaki et al. 1996; Faveeuw et al. 2000). ICAM-1, ICAM-2, and intercellular adhesion molecule 3 (ICAM-3) are counterreceptors for $\alpha_L\beta_2$ integrin whereas VCAM-1 binds weakly to $\alpha_4\beta_7$ and is the main ligand

Table 1 *Cell adhesion molecules involved in lymphocyte homing*

Cell adhesion molecule	Expression	Ligand	Adhesion step	Implicated in
Integrins				
LFA-1 ($\alpha_L\beta_2$, CD11a/CD18)	Most leukocytes	ICAM-1, -2, -3	Tight adhesion	General role in extravasation
$\alpha_4\beta_1$ (VLA-4)	Lymphocytes	VCAM-1, fibronectin	Tethering and tight adhesion	Leukocyte homing to inflamed tissue
$\alpha_4\beta_7$	Lymphocytes	MadCAM-1, fibronectin, VCAM-1	Tethering and tight adhesion	Lymphocyte homing to MALT
Selectins				
L-Selectin (MEL-14, CD62L)	Most nonactivated leukocytes	sLe^x on GlyCAM, CD34 and MadCAM-1	Tethering	Lymphocyte homing to LNs, leukocyte homing to inflamed tissue
P-Selectin (CD62)	Activated platelets, inflammatory endothelium	PSGL-1	Tethering	Leukocyte recruitment by inflamed tissue
E-Selectin (CD62E)	Inflammatory endothelium	CLA, PSGL-1, ESL-1	Tethering	Leukocyte recruitment by inflamed tissue
Ig superfamily				
ICAM-1	Inflammatory endothelium, activated lymphocytes	LFA-1, $\alpha_M\beta_2$	Tight adhesion	Leukocyte recruitment by inflamed tissue
ICAM-2	Endothelium and resting lymphocytes	LFA-1	Tight adhesion	General role in leukocyte extravasation
VCAM-1	Inflammatory endothelium	$\alpha_4\beta_1$, $\alpha_4\beta_1$	Tight adhesion	Leukocyte recruitment by inflamed tissue
MAdCAM-1	Mucosal endothelium	L-selectin, $\alpha_4\beta_7$	Tethering and tight adhesion	Lymphocyte recruitment to mucosal tissue
PECAM	Endothelium, leukocytes, platelets	PECAM, $\alpha_V\beta_3$	Diapedesis	Monocyte recruitment to inflamed tissues
JAM-1	Endothelium, epithelium, leukocytes, platelets	JAM-1, LFA-1	Tight adhesion and diapedesis	General role in leukocyte extravasation
JAM-2 (also called JAM3)	Endothelium, activated lymphocytes, platelets	JAM-2, VE-JAM, Mac-1	Adhesion and diapedesis	General role in leukocyte extravasation
Carbohydrate ligands of selectins				
GlyCAM (glycosylation dependent CAM)	High endothelial venules	L-Selectin	Tethering	Recruitment of naïve lymphocytes to lymph nodes
CD34	Endothelium	L-Selectin	Tethering	Recruitment of naïve lymphocytes to lymph nodes and inflamed tissue
CLA (cutaneous lymphocyte antigen, carbohydrate structure on PSGL-1)	Activated lymphocytes	E-Selectin	Tethering	Homing of lymphocytes to inflamed skin
MAdCAM-1 (mucosal addressin CAM)	Mucosal endothelium	L-Selectin	Tethering	Recruitment of lymphocytes to MALT
PSGL-1 (P-selectin glycoligand-1)	Myeloid, lymphoid and dendritic lineages	P-Selectin, E-selectin	Tethering	Homing to inflamed tissue
Others				
CD43	All leukocytes except mature B cells	Sialoadhesin-1	Negative regulation of tethering	Leukocyte migration and activation
CD44	Broad distribution	Hyaluronan	Tethering	Function in cell migration to inflamed areas
VAP-1	High endothelial venules, inflammatory endothelium	Amine oxidase activity on primary amino groups	Tethering	Recruitment of naïve lymphocytes to lymph nodes and inflamed tissue

Subdivisions are presented according to the molecular nature of the different protein, and their classification in different protein families. Although different classes of adhesion molecules mediate tethering, firm adhesion and diapedesis of lymphocytes involve exclusively integrins and their counterreceptors. See text for abbreviations.

(with fibronectin) for $\alpha_4\beta_1$ integrin. Therefore, $\alpha_4\beta_1$ is predominantly involved in the migration of lymphocytes to sites of effector functions, whereas $\alpha_L\beta_2$ plays a dual role in constitutive and inflammatory induced migration.

Firm adhesion of naïve lymphocytes

The importance of $\alpha_L\beta_2$ (LFA-1) integrin in homeostatic homing of lymphocytes has been demonstrated in α_L-deficient mice that show reduced numbers of lymphocytes in PLNs (Berlin-Rufenach et al. 1999). LFA-1-mediated adhesion is clearly a downstream event of rolling mediated by L-selectin and does not occur with nonrolling cells (Warnock et al. 1998). Interestingly, residual homing to lymph nodes in LFA-1-deficient mice appears to depend on lymphocyte α_4 integrins ($\alpha_4\beta_1$ and $\alpha_4\beta_7$) and VCAM-1 expressed by HEVs. However, the expression of VCAM-1 on HEVs under noninflammatory conditions is still controversial (Hahne et al. 1993; May et al. 1993; Berlin et al. 1995; Henninger et al. 1997). Real-time video microscopy studies have shown that the sticking fraction of lymphocytes on HEVs of peripheral lymph nodes (which do not express MAdCAM-1 and cannot undergo $\alpha_4\beta_7$-mediated adhesion) is not affected by blocking antibodies against α_4 integrin (Warnock et al. 1998).

In contrast to $\alpha_4\beta_1$, the dual role of $\alpha_4\beta_7$ integrin in rolling and firm adhesion of naïve lymphocytes on MAdCAM-1 is clearly established (Berlin et al. 1995). This was demonstrated using preactivated naïve lymphocytes which require only $\alpha_4\beta_7$ for arrest on the HEVs of Peyer's patches (Bargatze et al. 1995). Therefore, the specific engagement $\alpha_L\beta_2$ or $\alpha_4\beta_7$ with its respective ligand depends mainly on activation signals received by transmigrating cells (Campbell et al. 1998), as illustrated by numerous studies showing that the signals required for integrin clustering and stable adhesion differ between integrin α_4 and integrin β_2 (Constantin et al. 2000; Ding et al. 2001; Shamri et al. 2002).

Firm adhesion of antigen-primed lymphocytes

Once lymphocytes are activated in secondary lymphoid organs, they change their expression pattern of chemokine receptors and adhesion molecules, as demonstrated by phenotypic analysis of surface antigenic markers. Although the original names 'Very late Antigens, VLA' are no longer relevant for most integrins, $\alpha_4\beta_1$ (VLA-4) expression increases after long-term T-cell activation (Hemler 1990). In contrast, $\alpha_L\beta_2$ (lymphocyte function antigen-1 (LFA-1)) was initially identified as a T-cell costimulatory molecule involved in T-cell effector function (Kaufmann et al. 1982), before being shown to participate in lymphocyte adhesion to ICAM-1 and ICAM-2 on endothelial cells (Dustin and Springer 1988; van Kooyk and Figdor 2000). Therefore, in addition to selectin, the migration of lymphocytes at sites of inflammation is regulated by integrin engagement with their ligands ICAM-1 and VCAM-1. The latter are expressed within hours on endothelial cells stimulated by inflammatory chemokines, but their expression peaks within days (Haraldsen et al. 1996). The importance of ICAM-1 and VCAM-1 in lymphocyte migration at inflammatory sites has been formally demonstrated using antibodies and small molecules that inhibit the ligand-binding activities of the integrins $\alpha_L\beta_2$ and $\alpha_4\beta_1$, thus dampening inflammatory reactions (Isobe et al. 1992; Kakimoto et al. 1992; Yednock et al. 1992; Issekutz 1993). The central role of LFA-1 engagement with its counter-receptor ICAM-1 in inflammatory reactions is further demonstrated by the decrease in allogeneic response and delayed-type hypersensitivity in mice with a genetically engineered ICAM-1 expression deficiency (Sligh et al. 1993; Xu et al. 1994). The same transgenic approach has also been used to inactivate the different integrin chains (β_2, α_L, α_4, and β_1) and VCAM-1, confirming to some extent the role of these molecules in lymphocyte migration and inflammatory reactions (Arroyo et al. 1996; 1999; Coxon et al. 1996; Huleatt and Lefrancois 1996; Berlin-Rufenach et al. 1999; Potocnik et al. 2000). However, in the cases of α_4 and VCAM-1 deficiencies, unexpected defects in placental and heart development have also been reported (Kwee et al. 1995; Yang et al. 1995), suggesting a pleiotropic role of integrins in cell migration, differentiation, and organogenesis.

CHEMOKINES SHOW THE WAY

Although selectins and integrins are key mediators of cell arrest along the vasculature, they are not sufficient in determining the specificity of lymphocyte migration. The ability of a circulating leukocyte to employ integrins for tight adhesion is determined by the expression of chemokine receptors that, on ligand binding, signal to and thereby activate the available integrins (Table 2).

Interestingly, chemokines and their receptors show a much higher degree of tissue specificity than the adhesion molecules. As a result of the slow, selectin-mediated rolling (see above), the lymphocyte's chemokine receptors interact with chemokines presented by the glycocalyx of the endothelium. This mechanism collects the tissue-specific information by triggering $G_{\alpha i}$-protein-linked signaling events which activate the leukocyte integrins. Activated integrins then mediate tight adhesion of the lymphocyte to vascular endothelium of tissue specific lymphoid organs, and this is followed by migration into the tissue (Pachynski et al. 1998). The secretion of chemokines by inflammatory tissue may bypass tissue homeostatic lymphocyte homing. This can occur anywhere in the body and it efficiently redirects the migration of lymphocytes. Furthermore, the ability of lymphocytes to respond to

Table 2 *Chemokine receptors and their ligands*

Receptor	Ligands (old name)	Expression profile lymphocytes	Functional role for lymphocytes	Condition of function
CXCR3	CXCL9 (MIG)	Activated Th1 cells < Th2, B cells	Recruitment of lymphocytes to Th1-type inflammation	Inflammation
	CXCL10 (IP-10)	NK cells		
	CXCL11 (I-TAC)			
CXCR4	CXCL12 (SDF-1)	Progenitor cells, resting T and B cells	Emigration of B cells from bone marrow, stem cell, and thymocyte homing	Constitutive
CXCR5	CXCL13 (BCA-1, BLC)	B cells, memory T cells	Lymphocyte migration to B-cell follicles	Constitutive
CXCR6	CXCL16	Memory T cells	Migration of Th1 cells to inflammatory tissue	Inflammation
CCR1	CCL3 (MIP-1α)	Memory T cells	Migration of T cells to inflammatory tissue	Inflammation
	CCL5 (RANTES)			
	CCL7 (MCP-3, MARC)			
	CCL14 (HCC-1, CKβ1)			
	CCL15 (MIP-5, HCC-2, Lkn-1)			
	CCL16 (HCC-4, LEC, Mtn-1, LCC-1)			
	CCL23 (MPIF-1, ckβ8-1, ckβ-8)			
CCR3	CCL5 (RANTES)	Activated Th2 > Th1 cells	Migration of T cells to Th2-type inflammation	Inflammation
	CCL7 (MCP-3, MARC)			
	CCL8 (MCP-2)			
	CCL13 (MCP-4)			
	CCL15 (HCC-2, Lkn-1, MIP-5)			
	CCL24 (MPIF-2, eotaxin-2)			
	CCL26 (MIP-4α, eotaxin-3)			
CCR4	CCL17 (TARC)	Activate Th2 > Th1 cells	Migration of T cells to Th2-type inflammation	Inflammation
	CCL22 (MDC, STCP1, abcd-1)			
CCR5	CCL3 (MIP-1α)	Progenitors, activated Th1 cells	Migration to Th2-type inflammation	Inflammation
	CCL4 (MIP-1β)			
	CCL5 (RANTES)			
CCR6	CCL20 (LARC, MIP-3αEXODUS)	Memory T cells	Migration to inflammatory skin and other tissue	Inflammation
CCR7	CCL19 (ELC, MIP-3β, β11)	Resting and activated T cells, B cells	Migration to secondary lymphoid organs	Constitutive
	CCL21 (6Ckine, SLC, ckβ9)			
CCR8	CCL1 (I-309)	Th2 cells	Migration to Th2-type inflammation	Inflammation
	CCL4 (MIP-1β)			
CCR9	CCL25 (TECK, ckβ15)	$\alpha_4\beta_7^+$ T cells, thymocytes, IgA-secreting B cells	Homing to the gut, thymocyte selection	Constitutive
CCR10	CCL27 (CTACK, ILC, ESkine)	CLA^+ T cells	Homing to skin	Constitutive
XCR1	XCL1 (lymphotactin, ATAC)	Recent activated T cells, B cells		Inflammation
	XCL2			
CX3CR1	CX3CL1 (fractalkine, neurotactin)	Activated T cells	Migration to inflammatory tissue	Inflammation

Chemokine receptors are proteins that contain a seven-transmembrane ('serpentine') spanning domain, which can associate with trimeric G-proteins of the Gαi family. Upon chemokine binding, these receptors trigger a $G_{\alpha i}$-mediated signaling cascade that can lead to the activation of leukocyte integrins (Zlotnik and Yoshie 2000). See text for abbreviations.

chemokines depends on the expression of the appropriate chemokine receptor (Table 2).

Homeostatic homing of lymphocytes

MIGRATION OF NAÏVE LYMPHOCYTES TO SECONDARY LYMPHOID TISSUE

On the search for antigens, thymus-emigrating naïve T cells have to enter secondary lymphoid organs. They enter through postcapillary venules made of high cuboidal cells, the HEVs. The HEVs themselves and nonlymphoid cells in T-cell-rich areas of lymph nodes, spleen, and Peyer's patches produce the chemokine CCL21/SLC (Gunn et al. 1998b). It triggers rapid activation of integrins LFA-1 and $\alpha_4\beta_7$ and arrests rolling lymphocytes by signaling through the CCL21/SLC receptor CCR7. T lymphocytes deficient in CCR7 show very poor homing to lymph nodes and Peyer's patches (Nakano et al. 1997; Campbell et al. 1998; Gunn et al. 1998b, 1999) and plt mice, which lack CCL21/SLC, show impaired lymphocyte homing (Gunn et al. 1999). After entering the lymphoid organ T cells they have to be correctly positioned. The chemokine receptor CCR7 is also involved in this positioning mechanism but here it uses both ligands, CCL21/SLC and CCL19/ELC (Cyster 1999). Endothelial and stromal cells in T-cell zones produce CCL21/SLC, and dendritic cells and macrophages in T-cell areas make CCL19/ELC. Some of the CCL19/ELC, however, is transcytosed across to HEVs and has also a small effect on T-cell entry into the organ (Baekkevold et al. 2001).

The chemokine responsible for entrance of naïve B cells into lymphoid organs is not known. It is certainly different from CCL21/SLC because absence of CCR7 and/or CCL21/SLC does not dramatically change B-cell homing (Forster et al. 1996; Gunn et al. 1999). Inside the organ, however, B cells use CXCL13/BLC and its receptor CXCR5 to migrate into lymphoid follicles (Forster et al. 1994, 1996; Ansel et al. 2000). Stromal cells and follicular dendritic cells produce CXCL13/BLC in B-cell-rich lymphoid follicles (Gunn et al. 1998a). On B-cell activation the expression of the CXCL13/BLC receptor, CXCR5, is downregulated, probably allowing emigration – release of activated or memory B cells from follicular zones and lymphoid organs.

Polarization and tissue-specific imprinting of lymphocytes in secondary lymphoid organs

NAÏVE LYMPHOCYTES

Naïve lymphocytes enter the different secondary lymphoid organs such as spleen, lymph nodes, Peyer's patches, or tonsils more or less randomly via the chemokine CCL21/SLC and its receptor CCR7. Encounter of antigens leads to activated/memory lymphocytes and to reprogramming of homing properties corresponding to the lymphoid organ microenvironment (Campbell and Butcher 2002; Kunkel and Butcher 2002). It is therefore conceivable that leukocyte subset-specific expression of chemokine receptors may help selectively to recruit only certain subsets of cells to peripheral or lymphoid tissues, e.g. T-cell activation in mucosal lymph nodes induces loss of CCR7 and the expression of CCR9, a receptor for the chemokine CCL25/TECK. This chemokine is abundantly produced by the small intestine and partly by the thymus, and leads to homing of activated or memory T cells to the gut. Alternately, T-cell activation in skin-draining lymph nodes leads to expression of CLA (a skin-specific selectin-binding molecule – see above) and the chemokine receptors CCR4 and CCR10 (Campbell et al. 1999; Kunkel and Butcher 2002). These receptors bind the chemokines CCL17/TARC and CCL27/CTACK respectively. Both chemokines are constitutively produced by cutaneous epithelial cells and induce skin homing of lymphocytes expressing CCR4 and CCR10.

ANTIGEN-ACTIVATED LYMPHOCYTES

Activated/memory T cells were first thought to be mostly CCR7, i.e. unable to re-enter lymphoid organs. This was revised by the finding that $CCR7^+$ and $CCR7^-$ cells existed in these populations and led to the concept that central and effector memory T cells exist (Sallusto and Lanzavecchia 2000). In addition to the tissue-specific chemokine receptors, central memory cells retain their expression of CCR7 and L-selectin and can home back to lymphoid organs to participate in activation of naïve B and T cells. However, this concept has recently been challenged by the finding that cytokine-producing effector cells express CCR7 and migrate back to lymphoid organs (Kim et al. 2001; Debes et al. 2002; Unsoeld et al. 2002). Nevertheless, a large proportion of effector memory or long-term-activated cells lack CCR7 and L-selectin, and migrate to peripheral organs. Both populations may migrate to sites of inflammatory reactions. The $CD4^+$ T cells are of either central or effector subtype whereas $CD8^+$ T cells are mostly of effector type.

T-HELPER 1 VERSUS T-HELPER 2 LYMPHOCYTES

In addition to tissue-specific imprinting activated/memory, CD4 T cells in lymphoid organs polarize their function into T-helper 1 (Th1) and T-helper 2 (Th2) cells (Kim et al. 2001). The Th1 cells secrete cytokines such as lymphotoxin and IFN-γ to promote mainly antiviral cellular immune responses. Th2 cells release IL-4, IL-5, IL-6 and IL-13 to stimulate humoral immunity and allergic reactions, and to augment innate immune reactions. The expression pattern of chemokine receptors not only distinguishes the major lymphocyte subsets

from one another, but might also be in fact the key for differential migration characteristics of Th1 versus Th2 cells (Sallusto et al. 1998). Analysis of chemokine receptors on in vitro cultured lymphocytes has attributed expression of CXCR3 and CCR5 to Th1 and of CCR3 and CCR4 to Th2 (Sallusto et al. 1999). However, analysis of primary human T-helper cells revealed a chemokine expression pattern that was slightly more complex (Kim et al. 2001). It showed that the only chemokine receptors that defined helper cell populations were CXCR3 on Th1 cells, and nonexclusive but prevalent expression of CCR4 on Th2 cells. Different subgroups of Th1 cells showed various expression levels of CCR2, CCR5, and CXCR6. With the exception of CCR4 none of the chemokine receptors was exclusive for Th2 cells, including CCR3 for which data are controversial (Imai et al. 1999; Romagnani et al. 1999). The receptors CXCR5, CCR7, and CCR6 were negatively regulated in respect to T-cell polarization, i.e. these receptors are expressed by T cells with reduced polarity such as Th0 cells. Recent data also showed that there are more $CCR7^+$ than $CCR7^-$ T-helper cells in the blood, and the authors concluded that CCR7 expression may be sufficient to enter lymphoid tissue but its presence did not prevent homing of polarized cells into peripheral, nonlymphoid tissue (Kim et al. 2001).

B LYMPHOCYTES

B lymphocytes show less subtle polarization than T cells. However, when B-cell precursors mature into antibody-secreting plasma cells they home to the splenic red pulp, lymph node medullary cords, and bone marrow, where they become resident. Upon differentiation plasma cells express the CXCL12/SDF receptor CXCR4 and they downregulate the CXCL13/BLC and CCL19/ELC receptors, CXCR5 and CCR7, respectively (Wehrli et al. 2001; Hauser et al. 2002; Kunkel and Butcher 2002). Thus, responsiveness to CXCL12/SDF-1 allows B plasma cells to home to secondary lymphoid organs and the bone marrow. Natural antibody-producing B1 cells, however, maintain CXCL13/BLC receptors and use them for migration to the peritoneal cavity and the omentum (Ansel et al. 2002).

Migration of antigen-primed lymphocytes to inflammatory tissue

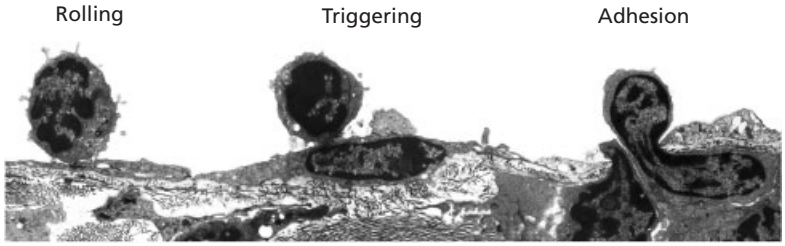
Inflammatory reactions locally induce the production of inflammatory chemokines by endothelial cells, epithelial cells, dendritic cells, resident macrophages, or other cells. Thereby, the type of inflammatory response is important and selects for the type of chemokines to be produced, e.g. acute Th1 reactions start by bacterial or viral infections that induce the secretion of IFN-γ, TNF-α, IL-1, or IL-12. These inflammatory cytokines stimulate the production of the CXCR3-binding chemokines CXCL10/IP-10, CXCL9/MIG, and CXCL11/I-TAC, and they attract mainly CXCR3-expressing Th1 cells. In contrast, allergic Th2 inflammatory reactions are induced by the cytokine IL-4 which leads to the production of the CCR4-binding chemokines CCL22/MDC or CCL17/TARC, attracting CCR4-expressing Th2 cells. However, subgroups of Th1 and Th2 cells express additional chemokine receptors that are less exclusive (see above). This has the consequence that lymphocytes recruited by inflammatory reactions show mixed populations with prevalent tissue-specific Th1 or Th2, skin- or gut-seeking cells.

DIAPEDESIS

Following rolling, triggering and firm adhesion is a final irreversible step of transmigration, also called diapedesis. The pathway used by transmigrating cells to cross the vascular barrier is still a matter of debate because there is evidence for both transcellular and paracellular migration of leukocytes (Muller 2001; Indrasingh et al. 2002). Therefore, the molecular mechanisms involved in this final step are still poorly understood even if recent findings suggest that molecules concentrated at interendothelial junctions regulate leukocyte transmigration, thus favoring the hypothesis that lymphocyte transmigration occurs at interendothelial contacts (Dejana et al. 2001; Aurrand-Lions et al. 2002; Luscinskas et al. 2002; Vestweber 2002). So far, interendothelial adhesion molecules playing a role in the control of leukocyte transmigration can be classified as follows:

- Proteins concentrated in intercellular contacts and interacting with counterreceptors on transmigrating cells such as PECAM-1/CD31, CD99 and JAMs (Muller et al. 1993; Martin-Padura et al. 1998; Cunningham et al. 2002; Schenkel et al. 2002).
- Structural molecules specifically incorporated in endothelial adherens or tight junctions which are involved in endothelial barrier function, such as VE-cadherin, occludin, or claudins (Allport et al. 2000; Burns et al. 2000; Kucharzik et al. 2001).

In contrast to claudin and JAM family members, which are not equally expressed by all endothelial cells (Morita et al. 1999; Palmeri et al. 2000; Aurrand-Lions et al. 2001; Liang et al. 2002), CD99 and VE-cadherin may play a role in both constitutive and inflammatory lymphocyte recirculation because they are expressed by the entire vascular tree. Therefore, one current hypothesis is that there is heterogeneity in the molecular composition of interendothelial junctions which are more or less permissive to lymphocyte transendothelial migration. Furthermore, the combination of intercellular adhesion molecules found in interendothelial contacts varies with endothelial activation such as inflammation. Indeed, it has been described that inflammatory activation induces interendothelial junctional remodeling and



LN	L-Selectin/PNAd	CCR7/CCL21	LFA-1/ICAM-2

Figure 2 *The multistep paradigm. In the first step, cell adhesion molecules on leukocytes interact loosely with their ligands on the endothelial surface, leading to rolling and slowing down of the leukocyte in the bloodstream. This allows chemokines presented by the endothelial glycocalyx to bind to leukocyte chemokine receptors, thereby triggering the activation of leukocyte integrins. Such activated integrins bind to their respective ligands on the endothelial cells, arrest the leukocyte, and eventually mediate diapedesis. In this sequential process, each step depends on the preceding step, starting with the tethering that induces leukocyte rolling. Therefore, only the expression of a distinct combination of chemokine receptors and cell adhesion molecules allows a leukocyte to adhere to and transmigrate the endothelium at a given site. Inversely, the endothelium can selectively recruit a certain leukocyte subset by expressing the appropriate combination of cell adhesion molecules and chemokines. The boxes below the flow scheme indicate the cell adhesion molecules and chemokine receptors and their ligands (leukocyte/endothelium) implicated in each step of this adhesion cascade in different tissues. LN, lymph nodes; GALT, gut-associated lymphoid tissue; infl., skin and general inflammatory situations.*

redistribution of VE-cadherin, PECAM-1, and JAM away from interendothelial contacts (Romer et al. 1995; Rival et al. 1996; Ozaki et al. 1999; Wong et al. 1999; Shaw et al. 2001). This contributes to the specific regulation of lymphocyte emigration. Such a concept has been reinforced by the findings that JAM is a ligand for the lymphocyte integrin $\alpha_L\beta_2$ (LFA-1), and that its subcellular redistribution to the apical surface of endothelial cells influences its function in lymphocyte transendothelial migration (Ostermann et al. 2002). In contrast to the adhesive interaction of JAM with LFA-1, PECAM-1 homophilic interaction regulates integrin activation in endothelial cells or transmigrating leukocytes (Tanaka et al. 1992; Piali et al. 1993; Zhao and Newman 2001), suggesting that interactions between endothelial and transmigrating cells may have a dual role in adhesion and cellular signaling. Dissecting the specific and sequential contribution of adhesion molecules to this complex signaling network will certainly improve our understanding of the specificity of lymphocyte recirculation.

CONCLUSION

The scope of this chapter was to outline the concept and mechanisms of lymphocyte homing and recirculation and to discuss the underlying molecular functions of cell adhesion molecules, chemokines, and chemokine receptors. As suggested by the pioneering studies on lymphocyte recirculation, the integrated function of the immune system requires highly efficient and specific adhesive mechanisms. These properties are illustrated by the multistep paradigm where a lymphocyte can proceed to the next step only if the previous one occurred successfully. The repertoire of molecular specificity is given by the panel of adhesion molecules that support rolling and firm adhesion, but is also greatly enhanced by the complex network of chemokines/chemokine receptors (Figure 2), which constitute the fine-tuning of the specific migration. Finally, the last transmigration step starts to be analyzed with molecular tools, but its contribution to specificity, irreversibility, and control of lymphocyte recirculation is still poorly understood.

INTRODUCTION

That a highly integrated and finely regulated mucosal immune system exists alongside and separate from the peripheral immune system might at first seem redundant and puzzling. Why should such a separate and sophisticated system be necessary when the peripheral immune system already seems to ensure immunity for the host? The mucosal areas exceed over 400 m^2, which is 200 times larger than the skin surface, and this large area is consistently exposed to environmental antigens, allergens, and pathogenic microorganisms (McGhee et al. 1999). Thus, the mucosal immune system provides the first line of defense for the host. It is not, therefore, difficult to imagine that effective mucosal immune responses represents a central pathway to combat infectious diseases, including bioagents of mass destruction, e.g. category A microorganisms/exotoxins. There can be no doubt about the sophistication and elegance of the mucosal immune system. It presents a well-tuned, two-part defense, one more structured and localized and another more diffuse. In the first, foreign antigens are encountered and selectively taken up into highly structured sites for the initiation of both mucosal and systemic immune responses. In the second, diffuse collections of effector cells such as B and T lymphocytes, differentiated plasma cells, macrophages (MΦ), and dendritic cells (DC), as well as eosinophils, basophils, and especially mast cells, come into play. Together, the two produce either mucosal and serum antibody responses and T-cell-mediated immunity (CMI), on one hand, or systemic anergy, commonly termed 'oral' or 'nasal tolerance', on the other. Such a separate and sophisticated immune system may well have evolved as a major defense mechanism against mucosally encountered infectious agents as well as to attenuate mucosal inflammation through tolerance induction. This chapter focuses on the cellular and molecular aspects of the mucosal immune response, including the innate and acquired responses as well as cross-talk between them.

THE INNATE MUCOSAL DEFENSE SYSTEM

Innate defenses comprise a network of cells and molecules that encounter foreign antigens before the acquired immune response. Innate mucosal immunity includes the physical barrier provided by epithelial cells and cilia movement, mucus production, secreted molecules with antibacterial activity, and the cytolytic activity of natural killer (NK) cells. In concert, these innate mechanisms provide a first line of defense against exogenous antigens, allergens, and invading pathogens. These mechanisms also set the stage for the development of antigen-specific immune responses to antigens/pathogens that can be eliminated at the level of the epithelium itself.

Antimicrobial peptide defensins

A growing number of antimicrobial molecules, generally termed 'defensins', are produced by cells of the mucosal epithelium which contribute to the natural protection of mucosal surfaces. Defensins exhibit antimicrobial effects similar to antibiotics. These molecules are β-sheet peptides that generally contain between 30 and 40 amino acid residues and can be divided into α- and β-defensins (Figure 1). The α-defensins are smaller, because of two contiguous cysteine residues, whereas β-defensins have cysteines separated by six amino acids; as a result of disulfide bonding the defensins are complexly folded microcyclic molecules. Paneth cells in the crypt regions of the small intestine possess secretory granules that are rich in α-defensins, often termed 'cryptidins', and additional antimicrobial peptides are secreted into the lumen of the crypts. It should be noted that the crypt regions are normally sterile; however, infection, e.g. by gram-negative pathogens, may result in cryptidin production to combat the pathogen. Two α-defensins, the human intestinal defensins (HD) HD-5 and HD-6, were identified in Paneth cells and the human reproductive tract (Ouellette 1997; Porter et al. 1997) (Figure 1). α-defensins are also secreted by tracheal epithelial cells and they are homologous to peptides that function as mediators of nonoxidative microbial cell killing in human neutrophils (human neutrophil peptides (HNP)) (Ouellette 1997; Porter et al. 1997). The β-defensins, and in particular human β-defensin (HBD)-1, are expressed in the oral mucosa, trachea, and bronchi, as well as mammary and salivary gland epithelial cells in humans (Zhao et al. 1996; Singh et al. 1998; Mathews et al. 1999) (Figure 1).

Defensins contribute to the protection of mucosal surfaces through their direct antimicrobial activity. It has been shown that two to four defensin molecules interact to form multimers that insert into the cell membrane of the target bacteria, where they induce membrane disruption. The resultant channel formation allows leakage of essential bacterial components and leads to death. The fact that adenovirus infection is impaired in cells expressing HBD-1 or HD-5 suggests that the microbicidal activity of mucosal defensins also applies to viruses (Gropp et al. 1999). There is abundant evidence that defensin expression is upregulated during infection, e.g. although bronchoalveolar lavage (BAL) fluids from normal patients express only HBD-1, those of patients

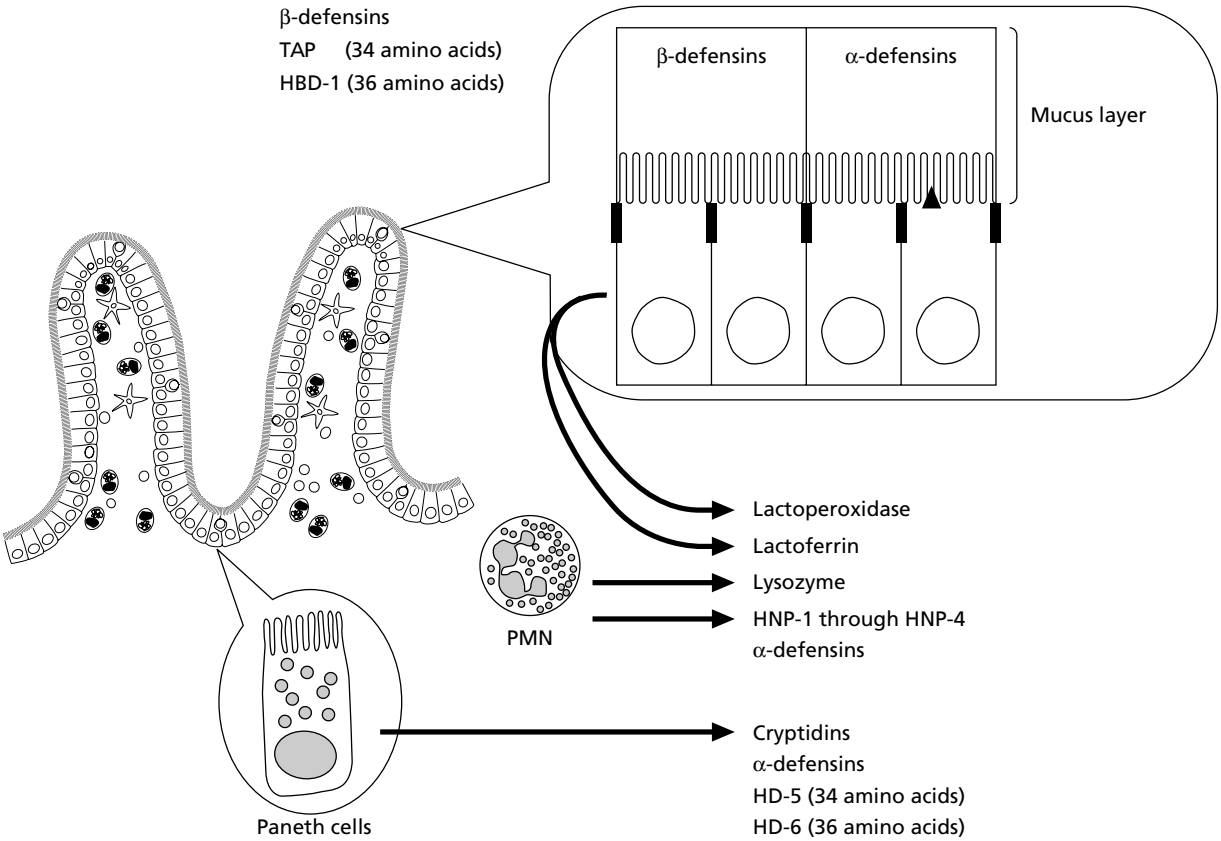

Figure 1 *Innate mucosal host defense factors: a thick coat of mucus prevents penetration of macromolecules and potential pathogens. The crypt regions contain Paneth cells, which produce cryptins (α-defensins). The β-defensins are products of epithelial cells and form a defensin network. Other innate factors such as lysozyme, lactoperoxidase, lactoferrin, and secretory leukocyte protease inhibitor (SLIP) also serve in antimicrobial defense. HBD, human β defensin; HD, human defensin; HNP, human neutrophil peptide.*

with cystic fibrosis (CF) or inflammatory lung diseases express both HBD-1 and HBD-2 (Singh et al. 1998). This expression of both HBD-1 versus HBD-2 in CF patients suggests a protective role for HBD-2 in inflammation. On the other hand, normal expression of HBD-1 may protect in the absence of inflammation. Mechanisms that control activation of defensins are poorly understood. Inflammatory cytokines, such as interleukin (IL)-1, tumor necrosis factor α (TNF-α), and lipopolysaccharide (LPS) have been shown to play a role in the induction of some defensins (Singh et al. 1998; Mathews et al. 1999). Metalloprotease matrilysin was recently reported to co-localize with α-defensins in murine Paneth cells (Wilson et al. 1999). Matrilysin was found to cleave the pro-segment from cryptidin precursors (Wilson et al. 1999), suggesting that this molecule regulates the antimicrobial activity of intestinal defensins. Recent studies showed that trypsin plays an important role as a prodefensin convertase in human Paneth cells in the regulation of innate immunity in the small intestine (Ghosh et al. 2002).

Lactoferrin, lysozyme, lactoperoxidase, and antimicrobial innate defense molecules

Other potent antimicrobial innate defense molecules are produced by epithelial cells and serve in natural host defense. These molecules include lactoferrin, lysozyme, the peroxidases, secretory phospholipase A_2, and cathelin-associated peptides. Some of these molecules are secreted by intestinal Paneth cells; all are produced by polymorphonuclear leukocytes (PMN), suggesting that both cell types play important roles in innate defense of mucosal surfaces. Lactoferrin is a member of the transferrin family and shares structural homologies with transferrin and ovotransferrin. This molecule is found in exocrine secretions including milk and saliva, and in lymphocytes of many species where it mediates a number of biological effects including antimicrobial properties. Epithelial cells do not produce lactoferrin; however, they express the lactoferrin receptor. Gastric pepsin hydrolysis of either human or bovine lactoferrin generates a 25-residue peptide called lactoferricin with potent antimicrobial activity (Bellamy et al. 1992). However, not all the 25 residues of lactoferricin are required for antimicrobial activity because an 11-residue peptide containing 5 of the 8 basic residues in bovine lactoferricin displays antimicrobial properties similar to those of the 25-residue peptide (Kang et al. 1996).

Lysozyme is a highly cationic, low-molecular-weight protein that enzymatically cleaves the bonds between *N*-acetylglucosamine and *N*-acetylmuramic acid which stabilizes bacterial peptidoglycans. High concentrations of lysozyme (1 209–1 325 μg/ml) are found in tears. Other secretions that contain lysozyme include saliva, human colostrum, serum, and urine (Pruitt et al. 1990). Human milk is particularly enriched in lysozyme with concentrations ranging from 20 to 245 μg/ml depending on the lactation period (Goldman et al. 1982). These concentrations are about 3000-fold higher than those found in cows' milk. Gram-positive bacteria are most susceptible to the antimicrobial activity of lysozyme, whereas gram-negative bacteria are generally resistant to this effect largely as a result of the protective effects of the outer membrane of LPS that masks the underlying peptidoglycan layer.

Peroxidase activity measured in many mucosal secretions is derived from an enzyme, human lactoperoxidase (hLPO), synthesized in the exocrine glands and secreted into mucosal surfaces. The PMNs also contribute to the peroxidase activity through secretion of myeloperoxidase (MPO) and eosinophil peroxidase (EPO). In this regard, human milk contains at least two peroxidases, the MPO from milk leukocytes and the hLPO produced by mammary gland ductal cells; both display similar properties to the human salivary peroxidases (hSPO) (Pruitt et al. 1991). Peroxidases protect by catalyzing the peroxidation of halides (Cl^-, Br^-, and I^-) and thiocyanate (SCN^-) ions to generate reactive products with potent antimicrobial properties. In the absence of halides and SCN^-, peroxidases can behave as catalases. These two properties of peroxidases prevent the accumulation of toxic products of oxygen reduction.

Secretory leukocyte protease inhibitor (SLPI), a 12-kDa nonglycosylated serine antiprotease, is a potent elastase, trypsin, and chymotrypsin inhibitor found in fluids lining mucosal surfaces, including the respiratory tract, salivary glands, and nasal and cervical mucosa (Mooren et al. 1983; Thompson and Ohlsson 1986; Franken et al. 1989; Hubbard and Crystal 1991; Westin et al. 1994). Thus, it has been shown that SLPI is produced by mucosal epithelial cells as well as goblet cells (Fryksmark et al. 1982; Maruyama et al. 1994; Asano et al. 1995). SLPI has been extensively studied for the protection it gives to the large airway epithelium of the human lung against neutrophil elastase. Thus, it has been suggested that SLPI would be a potential therapeutic tool in inflammatory lung diseases such as CF and pulmonary emphysema (Stolk et al. 1995). Further, SLPI-directed therapeutic genes showed potential roles for directing toxicity to carcinoma tissues (Garver et al. 1994).

Recently, human saliva itself showed an inhibitory effect for adherent primary monocytes infected with HIV-1Ba-L, and it has been shown that this anti-HIV activity was caused by SLPI (McNeely et al. 1995). In this regard, SLPI proved to be a potent inhibitor of translation in vitro. The mechanism of translation inhibition was deduced from in vitro experiments showing that SLPI bound to mRNA and interfered with the interaction of RNA-metabolizing enzymes, such as RNase (Miller et al. 1989). Furthermore, it has been suggested

that several inflammatory mediators such as TNF-α and phorbol myristate acetate (PMA) enhanced SLPI mRNA levels (Maruyama et al. 1994); however, the precise regulatory mechanism for the production of SLPI, such as the contribution of immune regulatory T cells and their derived cytokines, still remains unclear.

THE MUCOSAL EPITHELIUM BRIDGES INNATE WITH ACQUIRED MUCOSAL IMMUNITY

A major hallmark of the mucosal immune system is the presence of a mucosal intranet consisting of epithelial cells, αβT-cell receptor positive (TCR^+) T-helper 1 (Th1), T-helper 2 (Th2) cells, γδTCR^+ T cells and IgA-committed B cells for the induction and regulation of antigen (Ag)-specific secretory IgA (S-IgA) antibodies (Ab) in external secretions. The epithelium that covers mucosal surfaces largely consists of columnar epithelial cells because it is the major point of contact between localized environmental Ags in the gastrointestinal (GI) tract lumen and the underlying mucosal immune system. Epithelial cells not only provide a physical barrier but also produce and express a variety of glycoproteins, peptides, cytokines, and receptors that are important components of mucosal immunity. In addition, this epithelial layer contains a large number of $CD3^+$ T cells commonly termed intraepithelial lymphocytes (IEL). Both intestinal epithelial cells (IEC) and IELs are considered key players in the mucosal intranet and their contact leads to inter- and intracellular molecular communication. Thus, lymphoepithelial interactions contribute both to the maintenance of mucosal immunity and to homeostasis against infection.

Epithelial cells as a physical barrier

Mucosal surfaces are covered by a layer of epithelial cells that prevent the entry of exogenous antigens into the host. The physical protection of the largest mucosal surface, the GI tract, involves a monolayer of tightly joined absorptive epithelial cells termed 'enterocytes' which constitute a highly specialized selective barrier that allows the absorption of nutrients while preventing the entry of pathogens (Fujihashi and Ernst 1999). The intestinal epithelium also contains goblet cells, Paneth cells, and tuft cells, as well as undifferentiated crypt epithelial cells and IELs which contribute to the homeostasis of the epithelium and also serve physical barrier functions. The barrier effect of IECs is facilitated by the mucus blanket covering these cells and prevents the penetration of microorganisms and diffusion of molecules toward the intestinal surface. Mucus consists of glycoproteins of various molecular sizes (Roussel et al. 1988) secreted by goblet cells. These molecules resemble glycoprotein and glycolipid receptors that occur on enterocyte membranes and thus they tend to interfere with the attachment of microorganisms. In the human GI tract, the mucus blanket is approximately 100 μm in thickness. In the stomach and colon, however, this mucus blanket may range from 50 to 450 or 110 to 160 μm, respectively (Kerss et al. 1982; Sandzen et al. 1988). The continuous renewal of the epithelial cell layer also contributes to the barrier effect because damaged or infected enterocytes are replaced by crypt epithelial cells which differentiate into enterocytes as they migrate toward the desquamation zone at the villus tip. This process results in the complete renewal of the absorptive enterocyte layer every 2–3 days.

The epithelia of the other mucosal surfaces, including the oral cavity, pharynx, tonsils, urethra, and vagina, are covered by multilayered squamous epithelial cells. These epithelia lack tight junctions but provide a permeability barrier by secretion of a coating of glycolipoprotein into the intercellular space of the lower stratified layers (Farbman et al. 1988). A mucus blanket of approximately 2 μm covers the respiratory epithelium. Additional barrier effects are provided by the renewal of exposed epithelial cell layers by cells from subjacent layers. The final barrier provided by epithelial cells involves their transport of polymeric IgA (pIgA) via the pIg receptor (pIgR) with intracellular neutralization of viral particles (see below).

Cytokine and chemokine responses to mucosal pathogens

It has now been established that freshly isolated human colonic epithelial cells expressed mRNA for IL-6 and IL-8 (Jung et al. 1995). Further, epithelial cell lines have been useful for investigating the mechanisms that lead to proinflammatory cytokine and chemokine responses following a mucosal infection with pathogenic bacteria or viruses (Figure 2). In response to stimuli such as an *Escherichia coli* infection, epithelial cell lines of both intestinal (HT-29 and Caco-2) and urinary tract origin (A-498 and J82) produce IL-6 (Hedges et al. 1992; Agace et al. 1993). Further, fimbriae from *E. coli* also induce IL-6 production in these cell lines, suggesting that adhesive properties of the bacteria play an important role in the induction of this inflammatory cytokine (Figure 2). In addition, it has been shown that mucosal epithelial cell lines produce IL-8 after stimulation with *E. coli*, *Salmonella* spp., or *Listeria monocytogenes* (Agace et al. 1993; Eckmann et al. 1993a) (Figure 2). Others have shown that the adhesion of *S. typhimurium* to T84 human colonic epithelial cell lines induces the production of IL-8 (McCormick et al. 1993) and is associated with an increased transepithelial migration of neutrophils, although this process appears not to be regulated by IL-8 (McCormick et al. 1993). In addition, it has been reported that the mouse small intestinal

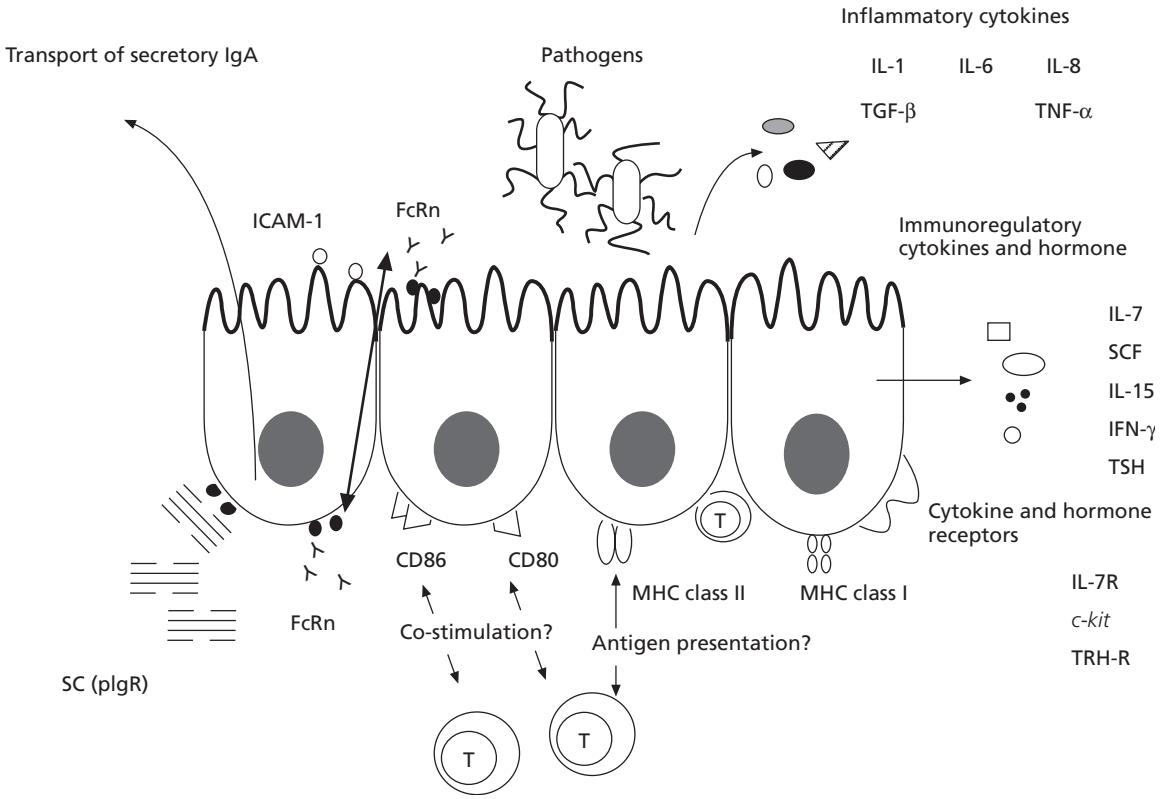

Figure 2 *Molecular interactions at the epithelial surface: the mucosal epithelial cells are essential for bridging innate and acquired immunity. The epithelial cells play important roles in both innate and acquired immunity. Cytokines and chemokines are induced by pathogens. Toll-like receptors (TLRs), which play key roles for pathogen-associated virulence factors are expressed by mucosal epithelial cells. The epithelial cells express accessory molecules (major histocompatibility complex [MHC] class I, II, CD80, CD86, CD1, and TL) and serve for antigen-presenting cell (APC) functions. Finally, antigen-specific secretory antibody (S-IgA) as well as IgG transport functions of the epithelial cells indicate essential roles in acquired immunity. cell line, MODE-K, produces stem cell factor (SCF) when infected with *S. typhimurium* (Klimpel et al. 1996) (Figure 2). Furthermore, invasive strains of bacteria, such as *S. dublin*, *Shigella dysenteriae*, *Yersinia enterocolitica*, *L. monocytogenes*, and enteroinvasive *E. coli*, induce colonic epithelial cell lines (T84, HT29, and Caco-2) to produce a characteristic array of proinflammatory cytokines, including IL-8, monocyte chemotactic protein-1 (MCP-1), granulocyte–macrophage colony-stimulating factor (GM-CSF), and TNF-α shortly after infection/stimulation (Jung et al. 1995) (Figure 2). A similar cytokine array was produced after infection with *Chlamydia*, but chemokine production was delayed and was dependent on infection of cultured cells (Rasmussen et al. 1997). *Helicobacter pylori* infection of gastric epithelium cell lines (Kato III, AGS, or MKN28), but not nongastric epithelial cell lines, induced IL-8 mRNA and protein synthesis (Crowe et al. 1995; Sharma et al. 1995). Immunohistochemical staining of human colon has demonstrated that IECs can express IL-6 and isolated IECs stimulated with LPS have been shown to contain mRNA for both IL-1 and IL-6 (Mayer et al. 1990). It was also shown that cholera toxin (CT)-induced inflammatory cytokines, such as IL-1 and IL-6, in the rat IEC line, IEC-17 (Bromander et al. 1993). Further, increased levels of SCF were also produced by the MODE-K cell line when stimulated with CT (Klimpel et al. 1995). Finally, respiratory syncytial virus (RSV) induced selective production of the chemokine RANTES in upper airway epithelial cells (Saito et al. 1997). Taken together, these studies suggest that epithelial cells are major players in both the inflammatory process and immunity, where they produce anti-inflammatory cytokine pathways.

The secretion of these factors is likely to be mediated initially in large part by interactions between components of microbes and pattern recognition receptors on the cell surface of the epithelium, which stimulate intracellular signals to initiate transcription of genes associated with the inflammatory cascade (Fearon and Locksley 1996). Recently, Toll-like receptors (TLR) have been shown to be key molecules for pathogen-associated virulence factors (e.g. LPS, peptidoglycan, and lipoprotein) and are considered to be major players in

innate immunity (Medzhitov et al. 1997; Gerard 1998). In this regard, it has been shown that TLRs are expressed by mucosal epithelial cells in the oral cavity, and the GI and respiratory tracts (Cario et al. 2000; Akira 2001; Asai et al. 2001; Wang et al. 2002) (Figure 2), e.g. individual bacterial components bind to specific TLRs, such as peptidoglycan (TLR-2 and TLR-4), lipoteichoic acid (TLR-2), or LPS (TLR-4) (Hoshino et al. 1999; Qureshi et al. 1999; Shimazu et al. 1999; Yoshimura et al. 1999). In addition, other TLRs bind to lipoteichoic acids from gram-positive bacteria (TLR-3), bacterial flagellin (TLR-5), and microbial CpG motifs of DNA (TLR-9) (Akira 2001). In the case of TLR-4, LPS recognition is coupled to CD14 binding wherein LPS bound to CD14 interacts with a TLR-4/MD-2 protein heterodimer (Asai et al. 2001). As breast milk contains soluble CD14 for the innate recognition of bacteria, it is possible that $CD14^-$ epithelial cells recognize LPS through soluble CD14 from milk (Labéta et al. 2000). The TLRs initiate an intracellular signaling cascade and induce activation of NF-κB, which regulates the epithelial cell cycle and subsequent production of soluble mediators (Aradhya and Nelson 2001).

Epithelial cell accessory molecules and antigen-presenting cell functions

In addition to the production of cytokines, IEC lines express adhesion molecules known to be required for antigen-presenting cell (APC) interactions with lymphocytes (see Figure 2). Both intercellular adhesion molecule-1 (ICAM-1) and lymphocyte function-associated antigen (LFA)-3 were constitutively expressed at low levels by human intestinal epithelial cell lines and expression of ICAM-1 was enhanced by exposure to the inflammatory cytokines interferon γ (IFN-γ), TNF-α, IL-1β, and IL-6 (Kvale et al. 1992). It was also shown that ICAM-1 expression on the apical side of epithelial cells was upregulated after infection with invasive pathogenic bacteria (Huang et al. 1996). Furthermore, gastric epithelial cell lines, as well as freshly isolated gastric epithelial cells, expressed both B7-1 (CD80) and B7-2 (CD86) (Ye et al. 1997) (see Figure 2). Thus, B7-2 expression was increased after crosslinking major histocompatibility complex (MHC) class II on IFN-γ-treated epithelial cells and in cells pretreated with IFN-γ and infected with *H. pylori*. These observations provide support for the finding that rat IECs present processed antigen to antigen-specific $CD4^+$ T cells (Brandeis et al. 1994). Taken together, the findings that epithelial cells express the adhesion molecules ICAM-1 and LFA-3 as well as B7-1 and B7-2, and present antigen to sensitized $CD4^+$ T cells, suggests that IECs probably play an important role in the maintenance of mucosal immune responses in mucosal effector sites and especially in the IEL compartment. It is also likely that IECs exhibit APC functions responsible for some forms of T-cell anergy in mucosal tolerance.

It has been shown that both intestinal and respiratory epithelial cells present antigen in both classic and nonclassic fashions to mucosal T cells (see Figure 2). Immunohistochemical analysis revealed that normal human IECs from the small intestine expressed HLA-DR, but less HLA-DP, and this MHC II expression was increased in inflammatory bowel disease (Mayer et al. 1991). Further, direct evidence for APC function was provided with studies of freshly isolated rat IECs and transfected epithelial cell lines, which presented a soluble allopeptide to primed T cells in an MHC II-restricted manner (Brandeis et al. 1994). Although uptake of antigen occurred at both apical (normal) and basal (inflammation) sides of IECs, peptide presentation to T cells through MHC II was seen only at the basolateral surface (Hershberg et al. 1998). Finally, nonclassic MHC I-restricted IEC presentation has been described. Thus, IECs express CD1d constitutively, which in turn is regulated by IFN-γ that also enhances classic MHC I and II molecule expression (Blumberg et al. 1991; Sydora et al. 1996a). The murine CD1 (mCD1) homolog of human CD1d may also bind to peptide antigen (Sydora et al. 1996b). Further, it was shown that mCD1 can bind to $CD8^+$ IELs, i.e. γδ and αβ TCR^+ T cells which express CD8αα homodimers (Sydora et al. 1996b; Gapin et al. 1999). Low numbers of CD1d-restricted NK T cells have been defined in the epithelium using CD1d tetramers (Matsuda et al. 2000). Other nonclassic MHC I molecules expressed by IECs have been directly linked to novel forms of co-stimulation (Leishman et al. 2001; Roberts et al. 2001). The expression of the thymus leukemia (TL) antigen by mouse IEC has been linked to ligation of CD8αα expressed on a subset of IELs, which then delivers a growth-promoting signal to the epithelium (Leishman et al. 2001).

Polymeric IgA and IgM, and monomeric IgG epithelial cell transport

A major function of epithelial cells in mucosal immune responses is the active transcellular transport of pIgA produced in mucosal and glandular tissues to the mucosal surface (see Figure 2). The molecule responsible for transport of pIgA into mucosal secretions is the pIgR (Mostov et al. 1980, 1984; Krajci et al. 1992). A major hallmark of the mucosal immune response is the presence of Ag-specific S-IgA Abs in external secretions. As discussed above, S-IgA Abs in humans occur as S-IgA1 and S-IgA2 subclasses, with a preponderance of the former in the upper respiratory tract (URT) and upper GI tract (GIT), and the latter in the lower ileum and large intestine (Mestecky and McGhee 1987; Brandtzaeg 1994). Plasma cells in lamina propria and

acinar regions of exocrine glands produce pIgA associated with the 15.6-kDa peptide J chain (Brandtzaeg 1974; Mestecky and McGhee 1987). Initially, it was thought that J chain was involved in polymerization of intracellular monomeric IgA (mIgA) or IgM (mIgM) (Brandtzaeg and Prydz 1984); however, recent studies indicate that aberrant polymers of IgM occur in the absence of J chain (Niles et al. 1995). Further, J chain knock-out mice exhibit IgA in external secretions; however, only mIgA is transported in this mouse (Hendrickson et al. 1995, 1996). Taken together, this suggests that J chain is required in the formation of pIgA and the correct pentameric form of IgM that enables the molecule to bind to pIgR on the basolateral side of the epithelium (Brandtzaeg 1974; Brandtzaeg and Prydz 1984; Hendrickson et al. 1995, 1996; Niles et al. 1995).

As indicated above, epithelial cells in glands and in basolateral crypts of the GIT and URT produce the full-length 100-kDa pIgR which associates with the nonserosal surface of epithelial cells (Mostov 1994). The binding of pIgA/pIgM is followed by endocytosis and transcytosis across the epithelial cell (Eckmann et al. 1993a). During transcytosis, disulfide bonds form between pIgR and pIgA and secretion of S-IgA follows cleavage of a 20-kDa component of pIgR and exocytosis – the entire process requiring less than an hour (Mestecky and McGhee 1987; Mostov 1994) (see Figure 1). The disulfide-bonded portion of the pIgR remains attached to the Ab molecule, termed secretory component (SC), stabilizes S-IgA and S-IgM, and renders the molecule more resistant to proteolytic digestion (Mestecky and McGhee 1987; Mostov 1994). This transport process is highly efficient and a normal adult produces 2.8–3.0 g S-IgA/day in the GIT alone.

A number of studies have provided evidence that IEC lines produce cytokines and express cytokine receptors and adhesion molecules that may affect the induction of mucosal immune responses. When human IECs were examined for their ability to produce cytokines, both cell lines and freshly isolated human IECs were shown to produce IL-8 (Eckmann et al. 1993a, b; Schüerer-Maly et al. 1994), and the former also expressed mRNA for IL-1α, IL-1β, IL-10, and TNF-α, but not for IL-2, IL-4, IL-5, IL-6, or IFN-γ (Eckmann et al. 1993a, b). It has now been shown that IFN-γ and TNF-α induced HT-29 cells to increase membrane-associated pIgR (Sollid et al. 1987; Kvale et al. 1988). Further, IL-4 enhanced the expression of surface pIgR, and this cytokine acted in synergy with IFN-γ to induce high levels of pIgR on HT-29 cells (Phillips et al. 1990). Taken together, these results suggest that IECs have the ability to produce cytokines that could play a role in the induction and maintenance of mucosal immune responses and inflammation.

The epithelium also expresses the neonatal Fc receptor for IgG (FcRn). It has been shown that FcRn is responsible for the passive acquisition of IgG neonatally in rodents (Israel et al. 1997; Zhu et al. 2001). Thus, it was predicted that FcRn expression was strictly limited to neonatal life. However, recent evidence indicates that this molecule is also expressed by adult human epithelium and by Mϕs in the intestinal lamina propria. When expressed postnatally in adult humans, FcRn may serve in a capacity to provide for the continuous presence of IgG Abs to prevent microbial infections. The FcRn binds monomeric IgG in a pH-dependent process (pH 6 on, pH 7.4 off) because of histidine residues in the Fc region of IgG. In contrast to the transport associated with pIgR, the pathway associated with FcRn goes from basal to apical as well as from apical to basal (Dickinson et al. 1999) (see Figure 2). In addition, the FcRn is not associated with proteolytic cleavage and is thus available for several rounds of transport. It is predicted, therefore, that the FcRn is a major player in the steady-state distribution of IgG on both sides of the epithelial barrier. Most feel that paracellular transport of this macromolecule does not occur because of the molecular exclusion of the tight junctions.

AN IEL–IEC INTRANET

Origin and function of intestinal IELs

The mucosal epithelium, an important interface between the host and its environment, contains a large number of $CD3^+$ T cells which are commonly termed IELs (Ernst et al. 1985; LeFrançois 1991; McGhee et al. 1994) (Figure 3). As the name IEL indicates, these lymphocytes reside on the basolateral surface of epithelial cells covering the GI, nasal, and reproductive tracts. It has been estimated that one IEL can be found for every four to six epithelial cells (Ferguson and Parrott 1972; Crowe and Marsh 1994). Thus, tremendous numbers of $CD3^+$ T cells are situated in the mucosal epithelium where they are continuously exposed to mucosally encountered antigens. Although human IELs share several unique features with mouse IELs, the phenotype of cell surface antigens is different, e.g. the most striking characteristic of mouse IELs is the presence of high numbers of γδ T cells (Ernst et al. 1985; McGhee et al. 1994); however, most human IELs express oligoclonal αβTCRs (Ebert 1994; Halstensen and Brandtzaeg 1994) (Figure 3). Despite the numerous studies that have focused on a better understanding of the ontogeny of murine IELs, only limited information is currently available about the origin and development of human IELs. Morphological studies have suggested that human IELs originate from cells in the lamina propria. Thus, it has been shown that they possess trailing cytoplasmic pseudopods in the direction of lamina propria (Orlic and Lev 1977). Further, the epithelial basement membrane around the site of IEL migration has specific pores

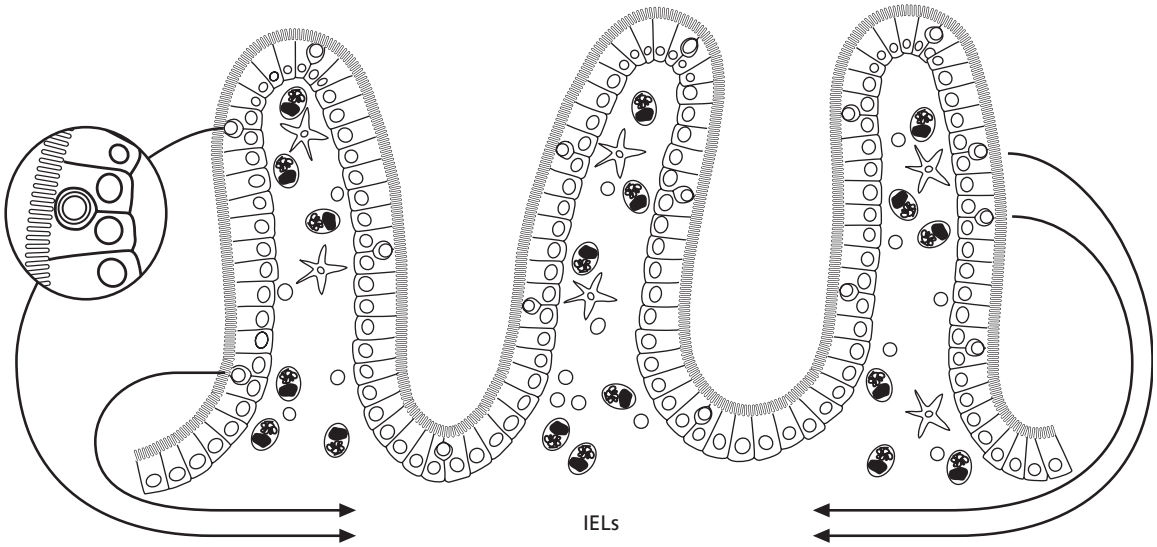

Figure 3 *Intraepithelial lymphocytes (IELs). Unique effector T-cell subsets are present in the epithelium. In this regard, the origin and immunological functions of IELs are distinct from other mature T cells. IECs, intestinal epithelial cells; TCR, T-cell receptor.*

(Toner and Ferguson 1971). These findings suggest that human IELs not only migrate from the lamina propria, but also have the potential to migrate back to this region. These observations further suggest that potential extrathymic development of human IELs may occur. Indeed, human IELs express CD7 (Fcμ receptor) which is also expressed on $CD3^-$ pre-T cells in the thymus (Malizia et al. 1985). These $CD7^+$ IELs contain small but significant numbers of $CD3^-$ IELs. In the case of γδ T cells in human IELs, Vδ2 expression also supports the possibility of extrathymic development. It has been shown that this T-cell population is rare in the gut although most fetal γδ IELs express the Vδ2 segment (Spencer and MacDonald 1994). In contrast, other reports showed that human IELs contain an equal frequency of Vδ1 and Vδ2. Despite the lack of a clear answer for the origin of human IELs, recent reports strongly suggest that patches that occur in the crypt region, termed 'cryptopatches', in the intestinal lamina propria of mice do not express lineage markers, including CD3, B220, Mac-1, Gr-1, and TER119, or *c-kit*$^+$ cells that allow differentiation into either αβ or γδ IELs (Kanamori et al. 1996; Saito et al. 1998).

IELs may be assumed to be a primary source of effector T cells in the natural environment of the mucosal epithelium. Such effector cells form a first line of defense against translocation of the mucosal microflora and invading microbial pathogens. The $CD8^+$/IEL T-cell subset is associated with cytotoxic activity (Ernst et al. 1985; LeFrançois 1991; McGhee et al. 1994), e.g. human $CD8^+$ IELs possess cytotoxic activity and kill a tumor epithelial cell line by mechanisms that are totally different from NK-type activity (Ebert 1994; Spencer and MacDonald 1994). It is important to note that cytotoxic activity in human $CD8^+$ IELs is restricted to epithelial cells. These findings clearly suggest that human $CD8^+$ IELs play an immune surveillance role in order to identify and remove defective or infected IECs. Cytotoxic activity in IELs has also been studied in detail in the mouse system. Thus, CTL activity for both αβ and γδ IELs was shown by use of a re-directed cytotoxic cell assay in hybridoma cell lines producing monoclonal antibodies (mAb) specific for $CD3^+$, $\alpha\beta TCR^+$, or $\gamma\delta TCR^+$ cells as targets (LeFrançois and Goodman 1989; Guy-Grand et al. 1991). Furthermore, it has been shown that MHC I-restricted virus-specific cytoxic T lymphocytes (CTL) can be induced in the intestinal epithelium of mice (London et al. 1987; Offit and Dudzik 1989).

Certain subsets of IEL T cells have been shown to contribute to regional host defense against intestinal infections with bacterial pathogens (Yamamoto et al. 1993; Emoto et al. 1996; Roberts et al. 1996). During

Listeria monocytogenes infection, IFN-γ production and target cell lysis by $CD8^+$ αβ T cells were essential for complete (sterile) clearance of this pathogen (Kaufmann 1993). It was also shown that both $CD4^+$ αβ and γδ T cells contribute to optimal protection after systemic challenge with *L. monocytogenes* (Kaufmann 1993). Studies in TCR-deficient mice suggest an important role for γδ T cells in immune responses to both intracellular bacteria and parasites (Mombaerts et al. 1993; Tsuji et al. 1994; Ladel et al. 1995). The γδ T cells were required for control of mycobacterial infection (Mombaerts et al. 1993) and also contributed to immunity after *Plasmodium yoelii* immunization, because γδ T-cell-defective ($TCR\delta^{-/-}$) mice failed to respond to these intracellular pathogens and succumbed to infection (Tsuji et al. 1994). The γδ T cells also play an accessory role in the late stages of protective immune responses to *Mycobacterium bovis* Bacillus Calmette–Guérin (BCG) (Ladel et al. 1995). Taken together, these findings show that intraepithelial T cells can serve as effector cells to protect from mucosal parasitic, bacterial, and viral infections.

The vast majority of γδ T cells occur in the epithelium of the small intestine of normal mice and as such could provide a key role in the maintenance of mucosal immunohomeostasis, in addition to regulation of immune responses to intracellular bacteria and parasites. Our previous studies suggested that γδ IEL T cells are important for the maintenance of mucosal IgA Ab responses in the presence of systemic unresponsiveness (or oral tolerance) induced by oral immunization (Fujihashi et al. 1992). Indeed, it was shown that γδ T cells serve an important regulatory role for mucosal IgA responses, because $TCR\delta^{-/-}$ mice possess normal numbers of functional αβ T cells, but display markedly decreased IgA Ab responses after oral immunization (Fujihashi et al. 1996b). Furthermore, recent studies have suggested that γδ T cells play distinct roles in the induction of both low- and high-dose oral tolerance (Ke et al. 1997; Fujihashi et al. 1999). Thus, γδ T cells play a significant immunoregulatory role in IL-10-mediated, low-dose oral tolerance induction, but are not essential participants in the induction of systemic tolerance to orally introduced Ags given in larger doses (Fujihashi et al. 1999).

IEL and IEC crosstalk at the intestinal mucosal barrier

It is logical to consider that epithelial cells and IEL T cells in mucosal tissues cross-regulate each other in order to provide a cellular and molecular network to induce and maintain appropriate immunological homeostasis. Thus, as discussed above, IECs and $CD8^+$ IEL T cells elicit increased levels of MHC I and CTL activity, respectively, after infection by pathogenic viruses. It has been shown that IEL T cells are also capable of producing an array of cytokines including transforming growth factor β (TGF-β) and IFN-γ which in turn induce high levels of MHC expression on IECs (Taguchi et al. 1990b; Barrett et al. 1992; Fujihashi et al. 1993a, b). Further, IEL T-cell-derived cytokines, including IFN-γ, IL-4, and TNF-α, have been shown to influence IEC functions such as the production of the pIgR (Kvale et al. 1988; Phillips et al. 1990). Intraepithelial γδ but not αβ T cells have been shown to moderate the growth and differentiation of IECs by the production of keratinocyte growth factor (Boismenu and Havran 1994) (Figure 4). Studies in $TCR\delta^{-/-}$ mice have emphasized the important role played by IEL γδ T cells in IEC growth. In $TCR\delta^{-/-}$ mice, the turnover of IECs in intestinal villi and the levels of MHC II expression were both lower than in mice of the same genetic background (Komano et al. 1995). These findings suggest that intraepithelial γδ T cells provide cytokines essential for the growth and proper functioning of IECs.

Regulation is bi-directional, because epithelial cells can also influence γδ T-cell development and function. It was recently demonstrated that cytokine signaling between IL-7 and its receptor (IL-7R) contributes to development and activation of IEL γδ T cells. It was shown that both human and murine IECs contain specific mRNA for IL-7 (Watanabe et al. 1995; Fujihashi et al. 1996a) (Figure 4). Flow cytometry analysis of IL-7R expression revealed that a subset of γδ T cells exhibit high mRNA levels (Fujihashi et al. 1996a) (Figure 4). Thus, co-cultivation of intestinal γδ T cells and recombinant IL-7 results in the activation of T cells for proliferative responses (Fujihashi et al. 1996a). Stimulatory signals provided by IL-7, and by the IL-7R pathway (between epithelial cells and γδ T cells), also induce IL-2R expression on γδ T cells. In addition, IL-2 provides a synergistic activation signal for further activation of γδ T cells. Mice that lack the common cytokine receptor γ chain (γc), which is a part of both IL-2R and IL-7R (Noguchi et al. 1993), manifest complete loss of γδ T cells (Cao et al. 1995; He and Malek 1996; Maki et al. 1996). Furthermore, although studies have also provided evidence for a lack of γδ T cells in IL-7 and IL-7R gene-deleted ($IL\text{-}7^{-/-}$ and $IL\text{-}7R^{-/-}$) mice (Cao et al. 1995; He and Malek 1996; Maki et al. 1996; Moore et al. 1996), direct comparison of $IL\text{-}7^{-/-}$ and $IL\text{-}7R^{-/-}$ mice provides a unique opportunity to demonstrate the importance of this pathway for intestinal γδ T-cell development. Intestinal γδ T cells were reduced when the IL-7 gene was deleted and completely disappeared in the absence of IL-7R (Fujihashi et al. 1997). These findings support the idea that epithelial cell-derived IL-7 is an essential cytokine for the development and activation of neighboring $IL\text{-}7R^+$ γδ T cells.

In addition to the IL-7-corresponding receptor cascade, a study with WBB6/F1-W/W^v (*c-kit*) and WCB6/F1-Sl/Sl^d (SCF) mutant mice has suggested that

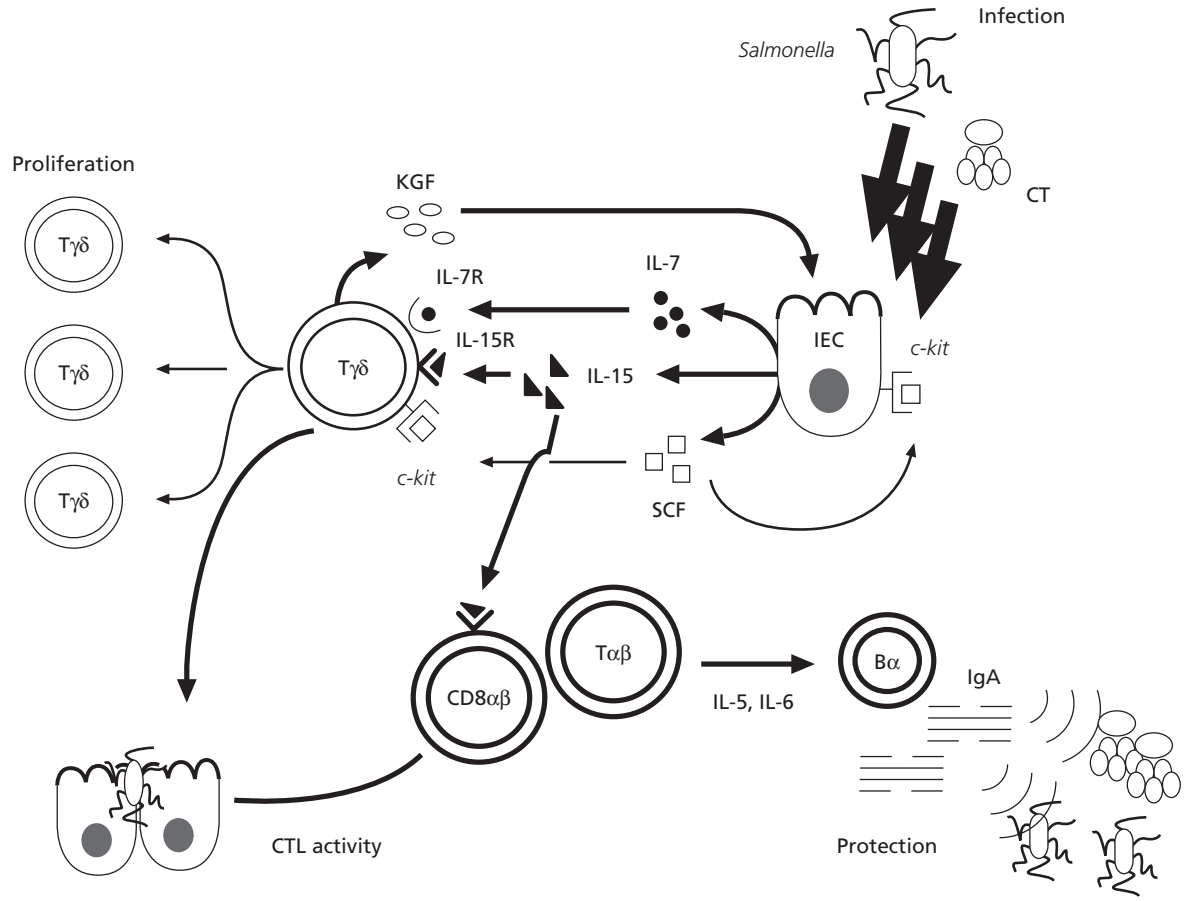

Figure 4 *The molecular intranet: a cytokine and growth factor intranet between epithelial cells and intraepithelial lymphocytes (IELs). Bi-directional regulation occurs between epithelial cells and γδ T cells for development and function. Intraepithelial γδ T cells have been shown to moderate the growth and differentiation of epithelial cells by the production of keratinocyte growth factor (KGF). Further, epithelial cells provide essential cytokines, interleukin IL-7, stem cell factor (SCF), IL-15 for γδ T cells, and thyroid-stimulating hormone (TSH) and IL-15 for CD8 αβ T cells. CTLs, cytotoxic T lymphocytes; IECs, intraepithelial cells.*

SCF and *c-kit* interactions also play important roles in the development and maintenance of IELs γδ T cells (Puddington et al. 1994) (Figure 4). Further, this study demonstrates that neighboring epithelial cells were able to produce SCF (Puddington et al. 1994) (Figure 4). Thus, although normal levels of γδ T cells were detected in IELs of both SCF and *c-kit* mutant mice at 4–8 weeks of age, decreased numbers of this T-cell subset were noted at 16 weeks of age (Puddington et al. 1994). These observations indicate that cross-talk between γδ IELs and IECs is essential for homeostasis of the mucosal immune system in the GIT. As SCF and *c-kit* are the products of IECs and IELs, respectively, this cytokine-signaling pathway from epithelial cells to intestinal γδ T cells is essential for the growth of mucosal γδ T cells.

The SCF and *c-kit* network has also been shown to be important for intestinal fluid secretion induced by *Vibrio cholerae* (Klimpel et al. 1995). Using a ligated intestinal loop model, it was shown that both *Sl/Sld* and *W/Wv* mice produced significantly less intestinal fluid in response to CT challenge than did control mice. The interaction of SCF with its receptor was further shown to be important in salmonella infections (Klimpel et al. 1996). Both human and murine IEC lines show enhanced SCF synthesis and expression of mRNA after exposure to *Salmonella* spp. (Klimpel et al. 1996). Thus, pretreatment of these cell lines with SCF increased their resistance to salmonella invasion (Klimpel et al. 1996). Further, when *c-kit* mutant and control mice were challenged with oral *S. typhimurium*, *W/Wv* mice were more susceptible to infection than were controls (Klimpel et al. 1996). These results show that interactions between SCF and *c-kit* play an essential role as a first line of defense at the mucosal epithelium. In the case of salmonella infection, it has been shown that IL-15 preferentially induces T-cell growth in peritoneal γδ T cells (Nishimura et al. 1996). These studies suggest that IL-15 is a potential growth factor for intestinal IEL γδ T cells. Indeed, other studies showed that IL-15 promoted the growth of IEL γδ T cells (Inagaki-Ohara et al. 1997). Further, it has been shown that gene deletion of the

IL-15 and IL-15R pathway resulted in reduced numbers of IEL γδ T cells in the intestinal epithelium (Lodolce et al. 1998; Kennedy et al. 2000).

Although IEC and IEL γδ T-cell interactions have thus far been the focus of this discussion, the role of IEL αβ T cells should not be ignored. This T-cell subset has the capacity to respond to IL-7 and SCF produced by IECs. In addition to participating in these cytokine signal pathways, IEL αβ T cells and IECs form a unique local hormone network (Wang et al. 1997). Thus, neuroendocrine hormones play an important role in the development of IEL CD8αβ$^+$, αβ T cells (Wang and Klein 1994, 1995). Mouse IECs express thyrotropin-releasing hormone (TRH) receptor and produce thyroid-stimulating hormone (TSH) upon TRH signal transduction, whereas IELs express TSH receptor (TSH-R)-specific mRNA (Wang et al. 1997). The phenotypic analysis of IELs in *hyt/hyt* mice, which have congenital point mutation in the TSH-R gene, revealed significant reductions in CD8αβ and αβ T-cell subsets but not the CD8αα fraction (Wang et al. 1997). In addition, recent studies showed significant development of CD8αβ$^+$, NK1.1$^+$ T cells in the IELs and subsequent induction of small intestinal inflammation by intestinal epithelium-specific IL-15 transgenic mice (Ohta et al. 2002). These results suggest the existence of additional important lymphoepithelial interactions, especially those involving intraepithelial CD8αβ$^+$, αβ T cells, and their important role in mucosal homeostasis and immunity. Taken together, epithelial cells and intraepithelial T cells are major players in the formation of a mucosal intranet and can reciprocally regulate each other via select cytokines and corresponding receptor interactions in order to provide and maintain an effective host defense system in the mucosal environment.

INDUCTIVE AND EFFECTOR LYMPHOEPITHELIAL SITES OF THE MUCOSAL IMMUNE SYSTEM

Organization of the mucosal immune system

The mammalian host has evolved organized secondary lymphoid tissues in the URT and GIT regions which facilitate antigen uptake, processing and presentation for induction of mucosal immune responses. Collectively, these tissues are termed 'mucosal inductive sites' (Figure 5). Although the gut-associated

lymphoepithelial tissues (GALT), e.g. Peyer's patches, the appendix, and smaller lymphoid aggregates called solitary lymph nodes (SLN), appear to be major inductive sites in all of the most common experimental mammalian systems, the degree of bronchus-associated lymphoepithelial tissue (BALT) developed at airway branches for defense against intranasal/inhaled antigens differs considerably among species (Pabst 1992; Kolopp-Sarda et al. 1994). Instead, the major inductive tissues for nasal/inhaled antigens in humans, primates, mice, and rats appear to be the palatine tonsils and adenoids (nasopharyngeal tonsils), which together form a physical barrier of lymphoid tissues termed 'Waldeyer's ring', now more frequently referred to as a nasopharyngeal-associated lymphoepithelial tissue (NALT) (Bernstein 1992; Kuper et al. 1992). To summarize, NALT and GALT in humans, mice, and primates and NALT, BALT, and GALT in other experimental mammalian systems comprise a mucosa-associated lymphoepithelial tissue (MALT) network (Bienenstock et al. 1978; Mestecky and McGhee 1987), the integration of which is only partly understood.

There are two major features that distinguish MALT from the other systemic lymphoid tissues. First, the epithelium that separates the tissue from the lumen contains a specialized cell type now called a microfold or M cell which is closely associated with lymphoid cells. Together this epithelial cell network is termed the follicle-associated epithelium (FAE). Second, MALT contains organized regions that include a subepithelial area (dome), B-cell zones with germinal centers containing IgA-committed B cells (surface IgA^+ ($sIgA^+$) B cells) and adjacent T-cell regions with APCs and high endothelial venules (HEV). Naive, recirculating B and T lymphocytes enter MALT through HEVs. Antigen-activated and memory B- and T-cell populations then emigrate from the inductive environment via lymphatic drainage, circulate through the bloodstream, and home to mucosal effector sites (via the common mucosal immune system (CMIS)) (Figure 5). These effector sites include more diffuse tissues where antigen-specific T and B lymphocytes ultimately reside and perform their respective functions (i.e. CMI, CTL, and regulatory functions or antibody synthesis) to protect mucosal surfaces.

Mucosal inductive sites

Mucosal inductive sites of the GIT include Peyer's patches, the appendix and SLNs, which collectively comprise the GALT (Bienenstock et al. 1978; Mestecky and McGhee 1987), while the tonsils and adenoids, or NALT, probably serve as the mucosal inductive sites for the URT, the nasal/oral cavity, and the genitourinary tract (Bernstein 1992; Kuper et al. 1992). The most extensively studied mucosal inductive tissues are the Peyer's patches of the murine GI tract, although, in recent years, several groups have also characterized NALT, albeit to a lesser extent than GALT, and salient characteristics of both are presented.

GUT-ASSOCIATED LYMPHOEPITHELIAL TISSUE

The initial steps involved in murine Peyer's patch development have been studied in some detail in mice. A cluster of $VCAM\text{-}1^+/ICAM\text{-}1^+$ cells occurs in the upper small intestine beginning at embryonic day –15 to –16 followed by the presence of cells expressing the IL-7 receptor ($IL\text{-}7R\alpha^+$) at day −17.5 (Adachi et al. 1997, 1998; Yoshida et al. 1999) which appear to be the anlage of the patch. Mice defective in IL-7Rα gene expression fail to form mature GALT (Yoshida et al. 1999). It now appears that IL-7–IL-7R triggering results in upregulation of $LT\alpha_1\beta_2$ membrane expression by lymphoid cells, including those in developing Peyer's patches (Rennert et al. 1996; Alimzhanov et al. 1997; Koni et al. 1997; Futterer et al. 1998). Further, mice that lack LT-α_1, LT-β_2 or that have been treated in utero with a fusion protein of LT-β receptor Ig (LT-β-R-Ig) fail to develop Peyer's patches or systemic lymph nodes (De Togni et al. 1994; Rennert et al. 1996; Alimzhanov et al. 1997; Koni et al. 1997; Futterer et al. 1998). In addition, lymphoplasia (*aly/aly*) mice, with a mutation in the NF-κB-inducing kinase (Shinkura et al. 1999), which appears to act downstream of LT-$\alpha_1\beta_2$-LT-βR signaling, also fail to develop Peyer's patches (Shinkura et al. 1999). There is recent evidence that a lymphoid progenitor cell from fetal liver expresses α4β7 and migrates to the Peyer's patch anlage where they ultimately develop into T cells, NK cells, DCs, and lymphotoxin (LT)-lineage cells (Yoshida et al. 2001). In humans, the Peyer's patches develop during prenatal life, a situation also seen in sheep, pigs, dogs, and horses (Griebel and Hein 1996).

Murine Peyer's patches contain a dome, underlying follicles (B-cell zones with germinal centers) (Figure 6a), and parafollicular regions enriched with T cells (Figure 6b). Originally, the specialized epithelial cell covering MALT was termed a 'FAE cell' because it characterized the organized lymphoid tissues in the GI tract and exhibited pinocytotic activity (Bockman and Cooper 1973). However, the M cell was later named for its unique topical morphology (microfold/membranous) (Owen and Jones 1974) and others now commonly describe the epithelium covering MALT as an FAE type because of characteristic M cells, lack of goblet cells, and close association with lymphoid cells (Wolf and Bye 1984; Farstad et al. 1994; Gebert et al. 1996; Neutra et al. 1996). The surface of the dome region is covered by the specialized FAE, 10–20 percent of which is made up of M cells that exhibit thin extensions around lymphoid cells (Bockman and Cooper 1973; Owen and Jones 1974; Wolf and Bye 1984; Farstad et al. 1994; Gebert et al. 1996; Neutra et al. 1996). extensions, which almost surround B and T lymphocytes and occasional macrophages (MΦ), form an apparent pocket (Farstad et al. 1994; Gebert et al. 1996; Neutra et al. 1996). The M cells, which have short microvilli, small cytoplasmic vesicles, and few lysosomes, are adept at uptake and transport of luminal antigens, including proteins and particulates such as viruses, bacteria, small parasites, and microspheres (Wolf and Bye 1984; Ermak et al. 1995; Gebert et al. 1996; Neutra et al. 1996). Investigators in this field disagree on whether M cells are able to process and present antigen. Some believe that antigen uptake by M cells and transcellular passage result in delivery of intact antigen into the underlying lymphoid tissue (Wolf and Bye 1984; Gebert et al. 1996). Others, however, contend that findings such as M-cell expression of MHC II molecules and acidic endosomal–lysosomal compartments suggest that M cells may also be involved in antigen processing and presentation (Allan et al. 1993). It is possible that the nature of endocytosed antigen influences M-cell activation and their potential to express MHC II molecules. In an important and elegant in vitro study, human Caco-2 cells, which are more immature enterocytes, differentiated into M-like cells when treated with mouse Peyer's patch T and B cells or with a human B-cell line (Raji) (Kerneis et al. 1997). Mice that lack B cells (termed μMT) were also shown to exhibit fewer M cells and less well-developed FAE and Peyer's patches than normal mice (Golovkina et al. 1999). These findings suggest that lymphocytes and especially B cells possess signaling molecules that induce M-cell differentiation.

In addition to serving as a means of transport for luminal antigens, the M cells also provide an entry way for pathogens. Invasive strains of *S. typhimurium* initiate murine infection by invading the M cells of the Peyer's patches (Jones et al. 1994). Although M cells are able to transport luminal antigen, noninvasive strains of *S. typhimurium* cannot penetrate M cells and thus are avirulent. Reoviruses also initiate infection of the mouse through the M cell (Wolf et al. 1981), an ability that has been associated with the reovirus sigma protein (Nibert et al. 1991). As discussed in more detail below, NALT also has a lymphoepithelium with M cells, and the tubercle bacillus *M. tuberculosis* uses this cell type for entry into the host with subsequent uptake in draining lymph nodes (Teitelbaum et al. 1999). Identification of bacterial and viral virulence factors associated with invasion or infection of M cells may provide tools to construct more efficient attenuated bacterial or viral vectors (see below) or to target mucosal vaccines to the inductive environment of MALT. Further, it is possible that M cells are also involved in the induction of mucosally-induced tolerance (e.g. oral tolerance). If antigen deposition via MALT is essential for induction of systemic unresponsiveness, it is likely that optimization of antigen delivery vehicles (including live vectors) that target M cells may improve immunization schema for development of mucosally induced tolerance.

The underlying dome region of the Peyer's patch consists of sparse plasma cells, as well as B and T lymphocytes (Gebert et al. 1996; Adachi et al. 1997), and this suggests that immediate antigen presentation may occur in the dome area after antigen uptake. It is also possible that T- and B-cell interactions in the dome area provide necessary protection for the Peyer's patch. The presence of MΦs (Sminia and van der Ende 1991) including the tingible body type suggests that significant apoptosis occurs, but is not yet proven. An immunohistological study has called into question whether dome MΦs are indeed a major cell type (Kelsall and Strober 1996). This important study has described a major APC population in the dome with characteristics of DCs (Kelsall and Strober 1996) (Figure 7). Interestingly, the dome DCs were $N418^+$ (anti-CD11c) and could be differentiated from more classic DCs present in the interfollicular area (T-cell zone), demonstrating that at least two DC subsets occur in key antigen-sampling areas of the Peyer's patch (Kelsall and Strober 1996). This study also suggested that fewer numbers of $B220^+$ B cells occur in the dome area of mouse GALT. Studies of the lymphocyte populations associated with human M-cell pockets, the area where luminal antigen may first be recognized by T and B lymphocytes, have also provided evidence for a characteristic T-cell distribution, e.g. M-cell pockets in human GALT contain approximately equal numbers of $CD3^+$ T and $CD19^+$/$CD20^+$ B lymphocytes with fewer $CD68^+$ macrophages (Farstad et al. 1994). Of the T cells in this location, approximately 75 percent exhibited a T-helper cell phenotype.

Distinct follicles (B-cell zones) are located beneath the dome area of the Peyer's patches and contain germinal centers where significant B-cell division is seen (Figure 6a). These germinal centers, which contain most of the $sIgA^+$ B cells (Butcher et al. 1982; Lebman et al. 1987; George and Cebra 1991; Weinstein and Cebra 1991; Weinstein et al. 1991), are considered to be sites where frequent B-cell switches to IgA and affinity maturation occur. However, unlike immune lymph nodes and the spleen in the systemic compartment, plasma cell development does not occur. All major T-cell subsets are found in the T-cell-dependent areas adjacent to follicles. The parafollicular T cells are mature and more than 97 percent of these T cells use the αβ heterodimer form of the TCR (Figure 6b). Approximately two-thirds of Peyer's patch αβ TCR^+ T cells are $CD4^+$, $CD8^-$ and exhibit properties of Th cells, including support for IgA responses (Kiyono et al. 1982a). Approximately one-third of the αβ T cells in GALT are $CD4^-$, $CD8^+$; this T-cell subset contains precursors of CTLs (London et al. 1987, 1990), whereas other $CD8^+$ T-cell subsets appear to contribute to mucosally-induced tolerance (see below).

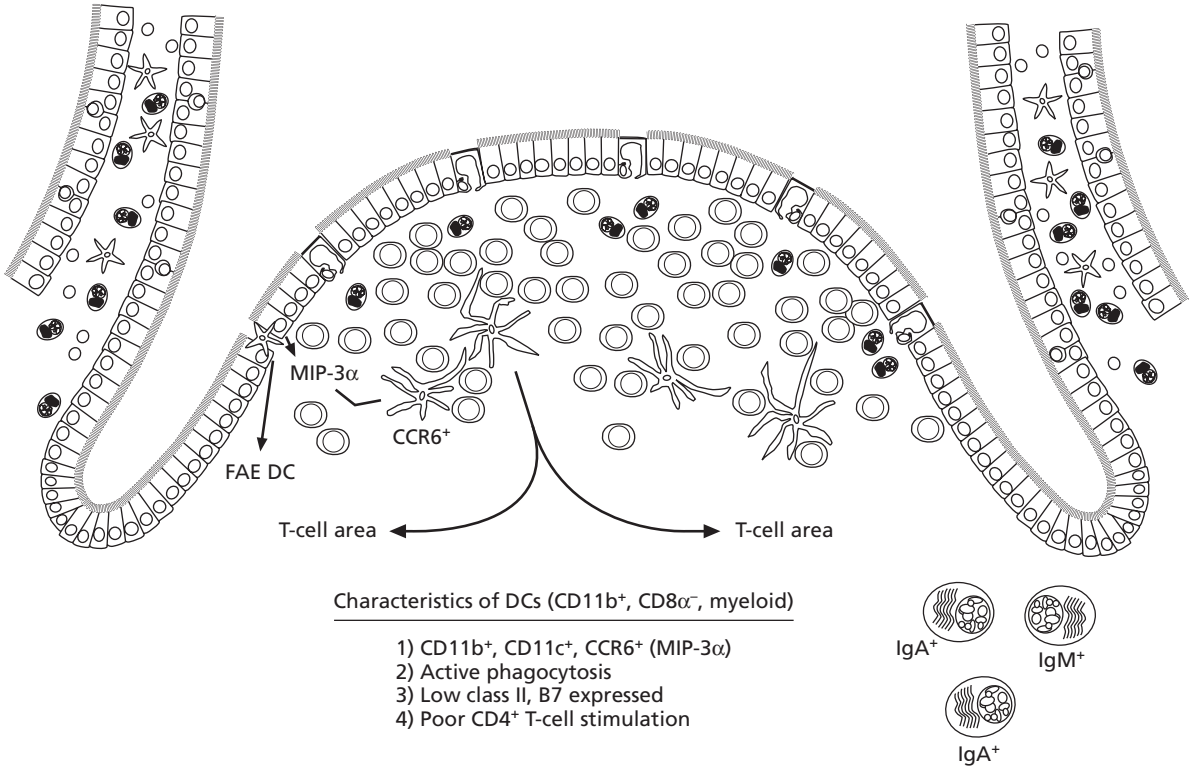

Figure 7 *Gut-associated lymphoreticular tissue (GALT) compartments: the subepithelial dome region of the Peyer's patch consists of sparse plasma cells, as well as B and T lymphocytes. A major antigen-presenting cell (APC) population in the subepithelial dome with characteristics of dendritic cells (DCs) plays a role in immediate antigen presentation in the dome area after antigen uptake. FAE, follicle-associated epithelium.*

NASAL-ASSOCIATED LYMPHOEPITHELIAL TISSUE

Although the mouse has been the major model used to study Peyer's patches, the human tonsils are the most accessible secondary lymphoid tissue for study of NALT and, as such, a great deal is known about the component cells (see Figure 5). Although the palatine and nasopharyngeal tonsils (adenoids) are largely covered by a squamous epithelium and are often not appreciated as mucosal tissues, the palatine tonsils usually contain 10–20 crypts that increase their surface area. The deeper regions of these crypts contain M cells, which may take up encountered antigens (Owen and Nemanic 1978; Allan et al. 1993). The tonsils contain all major classes of APCs including DCs and Langerhans' cells, MΦs, class II^+ B cells and antigen-retaining, follicular DCs in B-cell germinal centers (see Figure 2). Tonsillar APCs are capable of inducing T-cell proliferative and cytokine responses following in vitro restimulation with appropriate vaccines such as tetanus and diphtheria toxoid and purified protein derivative (PPD) of *M. tuberculosis*.

Approximately half of tonsillar cells are B lymphocytes and mainly occur in follicle-containing germinal centers. Most human tonsillar B cells are actually surface IgG-positive ($sIgG^+$); however, significant numbers of $sIgM^+$ and $sIgA^+$ B cells are also present. Further, in situ staining of B-cell blasts/plasma cells indicate a predominance of IgG blasts in germinal centers and of plasma cells in the parafollicular area. The overall ratio of Ig^+ cells was 65:30 for IgG versus IgA (Brandtzaeg et al. 1978; Boyaka et al. 2000). The human palatine tonsil also contains a distinct subepithelial B-cell population which differs from both germinal center and follicular mantle B cells (Dono et al. 1996a, b). This subset may represent the homolog of the extrafollicular B cells of the splenic marginal zone (Dono et al. 1996a, b). It is not accurate to suggest that the tonsils are only a mucosal IgA-inductive site, because of the presence of B cells committed to other isotypes, especially for IgG subclasses. Approximately 40 percent of tonsillar cells are T cells and more than 98 percent express the αβ TCR. Further, somewhat higher CD4:CD8 ratios are found in tonsils (3:1) when compared with peripheral blood or murine Peyer's patches. In summary, the tonsils clearly exhibit not only features of mucosal inductive sites, but also characteristics of effector sites with high numbers of plasma cells. The role of the tonsils in host mucosal immunity after intranasal immunization is not yet established.

To understand the precise contribution of NALT to the induction of IgA responses to inhaled antigens, studies in both mice and rats have established a NALT-like structure (Kuper et al. 1992; Asanuma et al. 1995;

Wu et al. 1996). The NALT consists of bilateral strips of nonencapsulated lymphoid tissue underlying the epithelium on the ventral aspect of the posterior nasal tract and exhibits a bell-like shape in cross-sections (Kilian and Russell 1994; Wu et al. 1997; Hiroi et al. 1998). Although dense aggregates of lymphocytes have been observed in the NALT of normal mice, germinal centers are absent, but could be induced by nasal application of antigen (Hiroi et al. 1998). Thus, uncommitted B cells ($sIgM^+$) have been found in high proportions (80–85 percent), whereas low numbers of $sIgA^+$ and $sIgG^+$ B cells (3–4 percent and 0–1 percent, respectively) have been noted in mononuclear cells isolated from NALT (Wu et al. 1996; Hiroi et al. 1998). In contrast to GALT where a high frequency (10–15 percent) of $sIgA^+$ B cells occur, NALT was found to contain fewer IgA-committed B cells. Despite this, nasal immunization induces much higher numbers of IgA^+ than IgG^+ NALT B cells in the memory compartment, showing the propensity of NALT for mucosal S-IgA Ab responses (McGhee et al. 1989). Characterization of isolated NALT mononuclear cells revealed that approximately 30–40 percent of these cells are $CD3^+$ T cells with a CD4/CD8 ratio of about 3.0 (Wu et al. 1996, 1997; Hiroi et al. 1998). The majority of NALT $CD3^+$ T cells co-express CD45RB, suggestive of naïve, resting T cells (Wu et al. 1996, 1997; Hiroi et al. 1998). As transcriptional single cell analysis revealed the expression of mRNA for both Th1 and Th2 cytokines, the majority of $CD4^+$ T cells are considered to be Thp or Th0 types (Hiroi et al. 1998). Further, stimulation via the TCR–CD3 complex resulted in differentiation of both Th1- and Th2-type cells. These results support the notion that NALT exhibits characteristics of mucosal inductive sites.

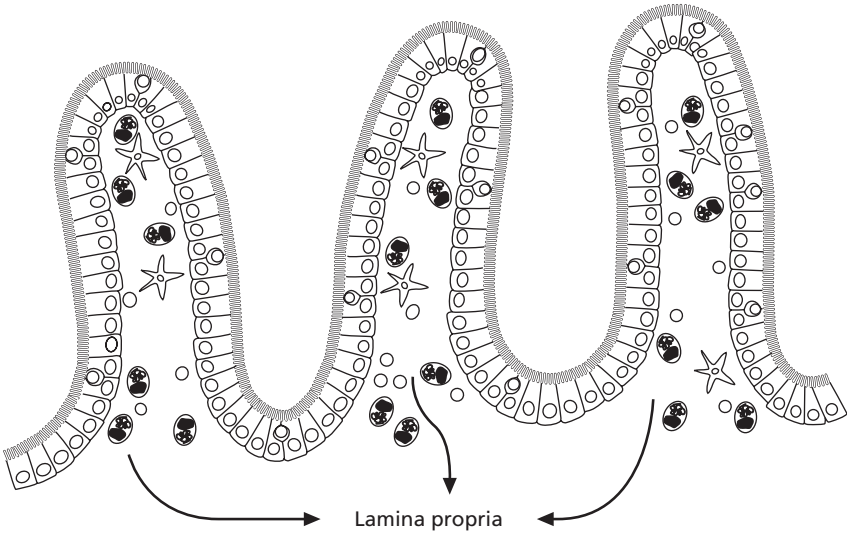
Mucosal effector tissues

After initial exposure to antigen in MALT, mucosal lymphocytes leave the inductive site and home to mucosal effector tissues. This pathway, which results in immunity at several mucous membrane sites, is referred to as the common mucosal immune system (CMIS) (see Figure 5). Effector sites for mucosal immune responses include the lymphoid cells in the lamina propria (LP) regions of the GI, URT, and reproductive tracts as well as secretory glandular tissues such as mammary, salivary, and lacrimal glands (Adachi et al. 1997). In addition, most evidence suggests that the lymphocytes that reside in the epithelium (i.e. IELs) also serve as effector cells; however, it has been difficult to define IEL functions precisely (see Figure 3). Antigen-specific mucosal effector cells include IgA-producing plasma cells as well as B and T lymphocytes. IgA is the primary Ig involved in protecting mucosal surfaces and is locally produced in effector tissues (Adachi et al. 1997). Again, the presence of antigen-specific S-IgA Abs at mucosal surfaces other than the inductive site where antigen uptake initially occurred is definitive evidence of the CMIS. Thus, it would suggest that immunization of either NALT or GALT could induce mucosal immune responses in all mucosal effector tissues.

Effector mechanisms employed to protect mucosal surfaces include CTLs, as well as effector $CD4^+$ Th cells for CMI (Th1) and for S-IgA Ab (Th2) responses (McGhee et al. 1989; Kilian and Russell 1994). Indeed, both CTL and S-IgA Ab responses have been associated with protection against infection at mucosal surfaces and both may be important for resistance to, or more importantly prevention of, mucosal infection with viruses including HIV (Staats et al. 1994). Although little information about protective $CD4^+$ Th1-CMI responses is available, mucosal CMI responses appear to be important in tolerance and in control of infections by intracellular pathogens.

It must be remembered, however, that effector sites, which must serve as a barrier against numerous environmental foreign antigens and mucosal pathogens with which the inductive sites need not contend, will offer mechanisms of protection significantly different from those seen in the inductive sites. The high concentration of IgA plasma cells (estimated at $>10^{10}$ IgA plasma cells per meter of human small intestine (Brandtzaeg and Farstad 1999)) has traditionally been viewed as the most distinctive trait of the immunity offered at these effector sites (Figure 8). As discussed below, the murine GI lamina propria has an almost equal distribution of peritoneal B1 B-cell-derived IgA plasma cells. Further, the lamina propria of the gut also contains more than 50 percent IgA plasma cells that are B2 GALT B-cell derived (see below). However, as important, if not more so, are the large numbers of B and T lymphocytes (e.g. lamina propria lymphocytes (LPL)), more than 60 percent of which are T cells (James et al. 1986; Abreu-Martin and Targan 1996). The importance of these cell types is discussed in detail below.

When presented with an environmental antigen, epithelial cells endocytose it and in some cases themselves express MHC II molecules, processing antigens with subsequent association of immunogenic peptides with MHC II (Mayer and Shlien 1987). It has also been shown that Langerhans-like cells occur on the luminal side of the intestine at epithelial junctions between epithelial cells which could also provide accessory functions (Huang et al. 2000). When confronted with microorganisms and even with soluble proteins that can transverse the tight junctions between epithelial cells, the APCs at the effector sites may process them and so induce B- and T-cell responses. Some have suggested that MHC II^+ $sIgA^+$ B cells may bind antigen through endocytic pathways, process, and present peptides to $CD4^+$ Th cells. Macrophages in LP regions could also function in this manner for more complex antigens.



B lineage	
$CD5^+$	~ 50%
$CD5^-$	~ 50%
Memory	~ 90%

$\gamma\delta TCR^+$	3–5%
$CD4^+$ Th:	60–70%
Th1	~ 40%
Th2	~ 60%
$CD8^+$ CTL	30–40%
Memory	~ 95%
Naive	~ 5%
Activated, $CD25^+$ blasts	20%

Figure 8 *Structural features and cellular characteristics of mucosal effector sites. The lamina propria is equally populated by B1 and B2 cells, both of which differentiate into IgA^+ plasma cells. Note that memory B and T lymphocytes occur in this compartment.*

Freshly isolated mouse intestinal LP $CD4^+$ T cells contain high numbers of IL-5-secreting Th2-type cells in addition to IFN-γ-secreting Th1-type cells, suggesting that the effector regions of the mucosal immune system are somewhat biased toward a Th2 phenotype (Taguchi et al. 1990a, b). Further, recent findings obtained by a single cell reverse transcriptase polymerase chain reaction (RT-PCR) analysis of $CD4^+$ T cells from murine nasal passages revealed a high frequency of $CD4^+$ T cells expressing Th2 cytokine-specific mRNA (Hiroi et al. 1998). In summary, mucosal effector tissues contain all the necessary cellular components including epithelial cells, Th1/Th2 type $CD4^+$ T cells, CTLs, and IgA-producing cells for a multilayer barrier against the numerous environmental foreign antigens and mucosal pathogens.

MUCOSAL T CELLS AND CYTOKINES

T cells and cytokines that influence IgA switching

It is known that cytokines exert profound influences on B-cell switching from sIgM, sIgD expression to downstream isotypes including IgG subclasses, IgE, and IgA. Clear evidence was presented that clones of T cells from murine GALT, when mixed with noncommitted $sIgM^+$ B cells, induced isotype switching to B cells expressing sIgA (Kawanishi et al. 1983a, b) (see Figure 6a). More recent studies have revealed that T-cell–B-cell interactions support B-cell switches and have postulated a major role for the CD40 receptor on germinal center B cells with CD40L on activated T cells (Fuleihan et al. 1993; Banchereau et al. 1994; MacLennan 1994). In terms of cytokines involved in IgA switching, the most definitive studies to date suggest that transforming growth factor-β1 (TGF-β1) is the major cytokine (Coffman et al. 1989; Sonoda et al. 1989) (see Figure 6a). The first studies showed that addition of TGF-β1 to LPS-triggered mouse splenic B-cell cultures resulted in switching to IgA, and IgA synthesis was markedly enhanced by IL-2 (Lebman et al. 1990a) and IL-5 (Sonoda et al. 1989). The effect of TGF-β1 was on $sIgM^+$, $sIgA^-$ B cells and was not the result of selective induction of terminal B-cell differentiation. It was shown that TGF-β1 induced sterile Cα germline transcripts (Coffman et al. 1989; Lebman et al. 1990b), an event that clearly precedes actual switching to IgA. Importantly, TGF-$\beta^{-/-}$ mice exhibit low levels of IgA^+ plasma

cells in effector sites and of S-IgA in external secretions, providing evidence that TGF-β1 is also important for μ → α switching in vivo (van Ginkel et al. 1999).

Although many presume that isotype switching to IgA (i.e. μ → α) occurs in mucosal inductive sites such as GALT, and that terminal differentiation into plasma cells producing IgA is a major event in effector sites, only indirect evidence is at hand to support these assumptions. In this regard, most studies of μ → α switching have been performed with nonmucosal lymphoid cells, e.g. splenic B cells, whereas in vitro studies of B-cell differentiation to IgA synthesis normally employ Peyer's patch B cells (a mucosal inductive site) to support the idea that this also occurs in effector mucosal sites, such as LP and exocrine glands. Moreover, cytokine knock-out mice have been employed to determine the relevance of particular cytokines for mucosal immunity, an approach discussed below. That this dogma of μ → α switching occurs only in mucosal inductive sites is challenged by several recent findings. The activation-induced cytokine deaminaseAID) gene, initially discovered in germinal center B cells (Muramatsu etal. 1999) has been cloned from B-lymphoma cells stimulated with CD40L, IL-4, and TGF-β1 which were undergoing μ → α switches (Muramatsu etal. 2000). Over-expression of AID in μ^+ B-lymphoma cells resulted in spontaneous class switching from IgM to IgA in the complete absence of TGF-β1 or other cytokines (Muramatsu etal. 2000). Mice defective in the AID gene ($AID^{-/-}$) and humans with AID deficiency exhibit a hyper-IgM syndrome with no evidence of downstream switching (Muramatsu et al. 2000; Revy et al. 2000). However, recent studies revealed that $AID^{-/-}$ mice have a subset of $B220^+$ surface IgA^+ B cells in lamina propria (an effector site), and the presence of circles of 'looped out' DNA suggest that μ → α switching had just occurred in this site (Fagarasan et al. 2001). Most recent reports have shown the presence of isolated lymphocyte follicles (ILF) in the LP that contain $sIgA^+$ B cells (Hamada et al. 2002). Thus, it is still possible that these ILFs are the sites of IgA switching. Along these lines, it was also recently revealed that B-cell-deficient, μMT mice also exhibit LP IgA^+ plasma cells, suggesting that switches to IgA can occur even during pre-B-cell development (Macpherson et al. 2001). These intriguing studies have used mouse models where class switching in germinal centers is absent. Thus, μ → α B-cell switches may occur throughout the mucosal immune system and in the complete absence of germinal centers.

T cells and their derived cyokines for IgA synthesis

$CD4^+$ T cells and cytokines are essential for the generation of IgA-producing cells, e.g. depletion of $CD4^+$ T-cell subsets in vivo with mAbs or by knockout of the CD4 co-receptor gene markedly affects mucosal immune responses (Mega et al. 1991; Hörnquist et al. 1995). Loss of $CD4^+$ T cells is associated with diminished levels of IgA^+ plasma cells (Mega et al. 1991) and with deficient Th-cell-regulated IgA responses (Hörnquist et al. 1995). For B-cell terminal differentiation, IL-5 and especially IL-6, possibly in combination with other cytokines, appear essential for the continued presence of plasma cells undergoing high-rate secretion of IgA antibodies (Beagley et al. 1988, 1989; Harriman et al. 1988) (see Figure 6a).

Earlier studies revealed that addition of culture supernatants from DC–T-cell clusters, T-cell clones, or T-cell hybridomas to cultures of Peyer's patch or splenic B cells resulted in enhanced secretion of IgA (Spalding et al. 1984; Kiyono et al. 1985). One cytokine responsible for this activity was subsequently shown to be IL-5 (Coffman et al. 1987; Murray et al. 1987; Beagley et al. 1988; Harriman et al. 1988; Lebman and Coffman 1988; Lebman et al. 1990a). Removal of $sIgA^+$ B cells from Peyer's patch (PP) B-cell cultures abrogated IgA synthesis, demonstrating that this cytokine affected post-switched, IgA-committed B cells (Murray et al. 1987). No in vitro stimulus was required for Peyer's patch B cells and IL-4 did not further enhance the effect of IL-5 (Lebman and Coffman 1988). Taken together, these results suggest that IL-5 induces $sIgA^+$ B cells that are in cell cycle (blasts) to differentiate into IgA-producing plasma cells (Figure 9). Interestingly, another B-cell population, the peritoneal cavity B-1 cells, has been shown to contain precursors of lamina propria IgA^+ plasma cells (Kroese et al. 1989). Human IL-5 is thought to act mainly as an eosinophil differentiation factor and thus may have little effect on B-cell isotype switching and differentiation. It has been reported, however, that human B cells, when stimulated with the bacterium *Moraxella (Branhamella) catarrhalis*, could be induced by IL-5 to secrete IgA, and also possibly to undergo isotype switching to IgA (Benson et al. 1990). This effect could not be demonstrated using other more conventional B-cell mitogens, a finding that demonstrates the importance of the primary in vitro activation signal for B-cell switching.

The cytokine IL-6, when added to Peyer's patch B cells in the absence of any in vitro stimulus, causes a marked increase in IgA secretion with little effect on either IgM or IgG synthesis (Beagley et al. 1989) (Figure 9). In these studies, IL-6 induced two- to threefold more IgA than IL-5 (Beagley et al. 1989). The removal of $sIgA^+$ B cells abolished the effect of IL-6, demonstrating that, similar to IL-5, this cytokine also acted on post-switched B cells. Of relevance was the finding that human appendix $sIgA^+$ B cells express IL-6 receptors, whereas other B-cell subsets present do not. Further, appendix B cells were induced by IL-6 to secrete both IgA1 and IgA2 in the absence of any in

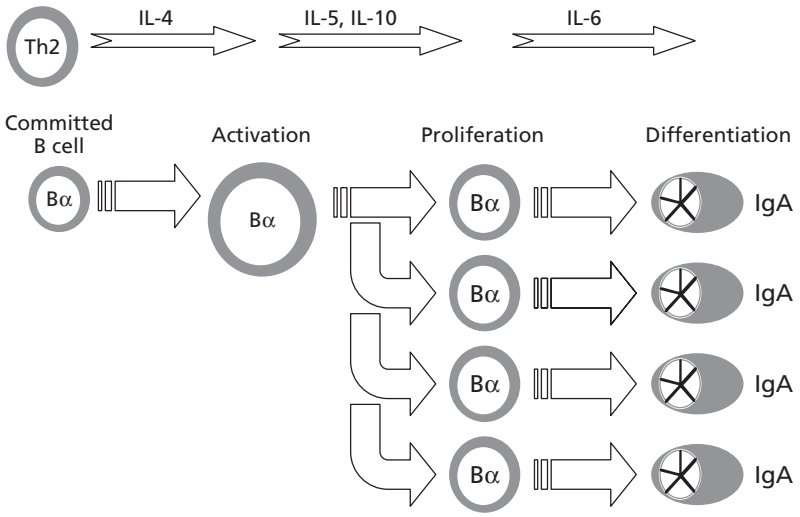

Figure 9 *Cytokine cascades in mucosal IgA immunity. T-helper 2 (Th2)-type cyokines clearly support the induction of IgA antibody responses. Interleukin-4 (IL-4) activates post-switched IgA-committed B cells and IL-5 induces sIgA$^+$ B cells which are in cell cycle (blasts) to differentiate into IgA-producing cells. IL-6 induces a marked increase in IgA secretion (two- to three-fold more IgA secretion than IL-5) when added to Peyer's patch B cells in the absence of any in vitro stimulus.*

vitro activation (Fujihashi et al. 1991) (Figure 9). This effect was also shown in IgA-committed B cells, again demonstrating the importance of IL-6 for inducing the terminal differentiation of sIgA$^+$ B cells into IgA-producing plasma cells. An additional Th2 cell cytokine, IL-10, has also been shown to play an important role in the induction of IgA synthesis in humans (DeFrance et al. 1992; Nonoyama et al. 1993; Briere et al. 1994). Taken together, these findings demonstrate that Th2 cell cytokines, such as IL-5, IL-6, and IL-10, all play major roles in the induction of IgA plasma cell responses.

INDUCTION OF MUCOSAL IMMUNITY AND VACCINES

Immune responses expressed in mucosal tissues are typified by S-IgA Abs (McGhee et al. 1999). This S-IgA constitutes the predominant Ig class in human external secretions, and is the best-known entity providing specific immune protection for mucosal tissues (Figure 10). The resistance of S-IgA Abs to endogenous proteases makes Abs of this isotype uniquely well suited to protect mucosal surfaces. Specific S-IgA

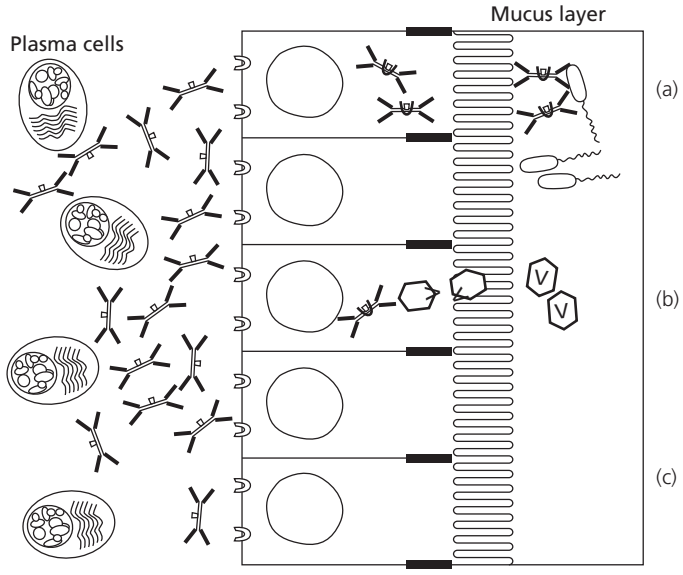

Figure 10 *The multiple functions of IgA: immunobiological function of antigen-specific secretory IgA antibody (S-IgA) for mucosal immunity. S-IgA constitutes the predominant immunoglobulin class in human external secretions and is the best-known entity providing specific immune protection for mucosal tissues.* **(a)** *Inhibition of adherence:* S. mutans, Vibrio cholerae, Shigella *spp.*, Escherichia coli, Giardia *spp.*, Haemophilus influenzae, *others;* **(b)** *Intracellular neutralization of:* rotavirus, Sendai virus, reovirus; **(c)** *removal of pIgA immune complexes.*

Abs provide classic 'immune exclusion' of noxious antigens. In addition, S-IgA prevents adherence of bacterial pathogens to epithelial cells and may also neutralize viral particles. Mucosal S-IgA Abs can serve as antitoxins to neutralize bacterial exotoxins, including enterotoxins and other potentially harmful molecules. In addition, S-IgA Abs may interfere with the utilization of growth factors for bacterial pathogens in the mucosal environment. Furthermore, it now appears that pIgA Abs, in the process of transport through the epithelial cell via the polymeric Ig receptor (pIgR), can also function to neutralize viruses and may also transport Ag–IgA complexes into external secretions (Ostov and Kaetzel 1999; Zhang et al. 2000). Taken together, it is essential to induce S-IgA Ab responses in order to provide effective mucosal immunity to environmental antigens, allergens, and infectious pathogens.

Mucosal APCs

Antigen presentation in mucosal tissues reflects the complexity of immune responses that occur in these sites. Indeed, the site of mucosal antigen uptake (i.e. M cells or epithelial cells) and the nature of antigen presentation that takes place will determine the outcome of the immune response. It is now well accepted that large macromolecules are taken up by M cells in the GI tract. It is controversial as to whether M cells express MHC II molecules and present antigen to immune effector cells (Hirata et al. 1986; Bjerke et al. 1993). However, as mentioned earlier, the presence of all three major APC types (i.e. memory B cells, MΦs, and DCs) in the dome epithelium of Peyer's patches make it likely that antigen uptake occurs immediately after release from M cells. Immunohistology of murine Peyer's patches have shown that $N418^+$, $2A1^+$, NLDC-145^-, $M342^-$ DCs form a dense layer of cells in the subepithelial dome (SED), just beneath the follicle epithelium where $CD3^+$ and $CD4^+$, but not $CD8^+$, T cells occur (Kelsall and Strober 1996) (see Figure 7). Another subset of DCs, $N418^+$, $2A1^+$, NLDC-145^+, and $M342^+$ DCs, was identified in the interfollicular T-cell regions where $CD3^+$, $CD4^+$, and $CD8^+$ T cells reside (Kelsall and Strober 1996). In contrast with DCs in the dome region, which express the phenotype of immature DCs (i.e. high endocytic activity and low levels of MHC and B7 molecule expression), those in the T-cell areas are mature, interdigitating DCs with low endocytic activity and high levels of MHC I and II as well as B7 molecules (Kelsall and Strober 1996). The presence of these separate populations of DCs suggest that antigen is taken up by M cells and is first endocytosed in the dome region by DCs which may migrate to T-cell areas to become mature DCs.

It has recently been shown that Peyer's patch DCs preferentially promote Th2-type cells (Iwasaki and Kelsall 1999), suggesting that these cells also influence the nature of immune responses initiated in the gut. Few MΦs occur in the SED; however, both B cells and MΦs were found in the interfollicular T regions of Peyer's patches and lamina propria of intestinal villi. In addition, memory B and T cells occur in the pockets formed by M cells, and may be initial sites of immune responses (Yamanaka et al. 2001). DCs are also found in the NALT where they seem to play the same role as in the GALT. In fact, DCs are found in human tonsils (Bernstein 1999). It has been shown that DCs are recruited into the respiratory epithelium during acute immune responses induced by bacterial, viral, and protein antigens (McWilliam et al. 1996). In this regard, although freshly isolated rat respiratory DCs preferentially supported $CD4^+$ Th2-type responses, induction of Th1-type cytokine-mediated immune responses was also seen after stimulation with antigens (Stumbles et al. 1998). Studies of this nature suggest a further compartmentalization/specialization for antigen presentation by classic mucosal APCs; however, much is still unknown about the transport of antigen from M cells to DCs, MΦs, and memory B cells.

Mucosal immunization

It is generally agreed that mucosal adjuvants or delivery systems are essential in order to induce mucosal immune responses. In this regard, two bacterial enterotoxins (i.e. CT and LT from *E. coli*) are now established as very effective mucosal adjuvants for the induction of both mucosal and systemic immunity to co-administered protein antigens. To circumvent toxicity linked to these enterotoxins, mutant CT (mCT) and mutant LT (mLT) molecules devoid of their toxic activity were generated by site-directed mutagenesis. This approach involves the introduction of single amino acid substitutions in the active site (i.e. the site responsible for the ADP-ribosylation activity) of the A subunit of CT or LT or in the protease-sensitive loop of LT. Further, attenuated pathogenic bacteria such as recombinant (r) *Salmonella* were also used as a mucosal delivery system for the induction of S-IgA Ab responses to delivered antigen.

It is now realized that the nature of the delivery system as well as the route of immunization influences the nature of Th cell subsets induced and markedly affect the outcome of systemic and mucosal immunity, e.g. use of native CT or nontoxic mutants of CT with vaccines given orally tends to induce $CD4^+$ Th2-type cells with characteristic serum IgG1, IgG2b, IgE, and IgA as well as mucosal S-IgA Ab responses (Xu-Amano et al. 1993; Marinaro et al. 1995) (Figure 11). On the other hand, oral immunization with recombinant bacteria, e.g. r*Salmonella*-expressing proteins, tends to induce not only $CD4^+$ Th1-type cells and CMI responses but characteristic $CD4^+$ Th cells as well. These $CD4^+$ Th cells produce cytokines such as IFN-γ and IL-10 which appear to support mucosal S-IgA Ab responses

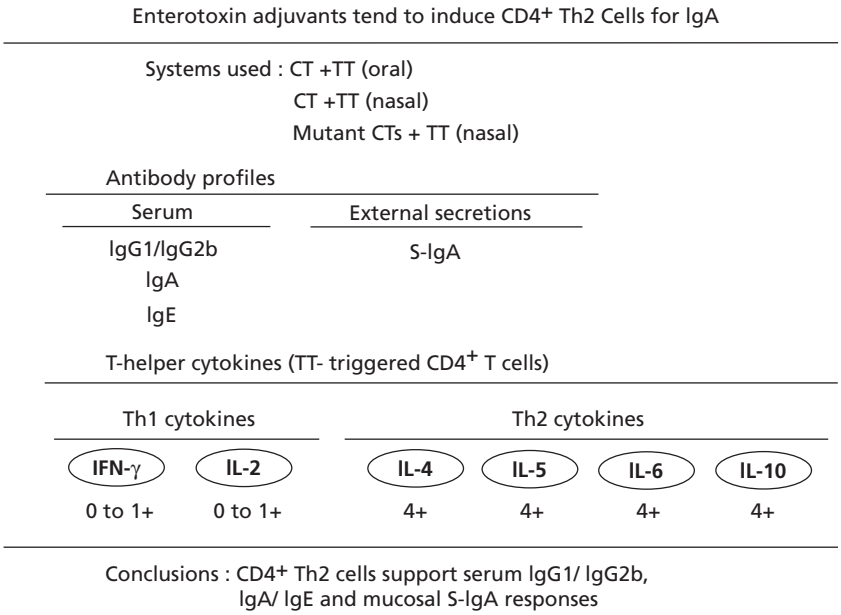

Figure 11 *T-helper 2 (Th2) cells for IgA responses. Th2-type cytokines mediate S-IgA Ab response induction. Use of native cholera toxin (CT) or nontoxic mutants of CT with vaccines given orally tend to induce CD4+ Th2-type cells with characteristic serum IgG1, IgG2b, IgE, and IgA as well as mucosal S-IgA responses.*

(Okahashi et al. 1996; VanCott et al. 1996). In this section, we have selected studies that illustrate the development of oral and nasal immunization strategies using either mucosal adjuvants or live vectors for mucosal vaccine development.

ORAL IMMUNIZATION

We have purposely selected a small subset of studies to illustrate the nature of murine immune responses which result from oral immunization with microbial vaccines. It is important to emphasize that immune responses vary depending on the nature of antigen used as well as mouse strains selected for study. However, proteins such as tetanus toxoid (TT) or hen egg white lysozyme (HEL) with CT as mucosal adjuvant induce predominantly serum IgG1 and IgE antibodies (Snider et al. 1994; Marinaro et al. 1995) (Figure 11). Further, in one study it was shown that systemic challenge of mice orally immunized with HEL and CT led to a fatal anaphylactic response (Snider et al. 1994). Thus, all studies that use CT or its mutant derivatives should be concerned with possible untoward reactions which may occur as a result of induction of IgE Ab responses. Oral immunization of mice with keyhole limpet hemocyanin (KLH) or TT and CT as adjuvant has been shown to induce Ag-specific $CD4^+$ Th cells with a characteristic Th2 phenotype (Wilson et al. 1991; Xu-Amano et al. 1993; Marinaro et al. 1995) (Figure 11), e.g. both PP and lamina propria lymphocytes, when restimulated with KLH, produced significant quantities of IL-4 and IL-5, with minimal levels of IFN-γ and IL-2 (Wilson et al. 1991). Thus, several studies now support the notion that oral immunization with soluble proteins and CT as adjuvant induces Th2-type responses, which provide help for characteristic serum IgG1 and IgE as well as mucosal S-IgA Abs. There is evidence that orally co-administered CT can also induce antigen-specific $CD4^+$ Th1-type responses, e.g. mice given a soluble preparation of *Toxoplasma gondii* on three occasions at 10-day intervals harbored splenic *T. gondii*-specific T cells (Bourguin et al. 1993). Further, in vitro restimulation resulted in increased levels of both IFN-γ and IL-2, whereas IL-4 and IL-5 levels were similar to those seen in mice orally immunized with *T. gondii* only (Bourguin et al. 1993).

A more revealing study used the mouse parasite *Trichuris muris* in a soluble form with CT and assessed IFN-γ and IL-5 levels as markers for Th1- or Th2-type responses respectively (Robinson et al. 1995). Interestingly, oral *T. muris* plus CT induced T cells that produced IL-5 before parasite challenge, but which switched to IFN-γ production after *T. muris* infection. This shift suggests that the infection itself results in $CD4^+$ Th1-type responses, even in the presence of a predominant Th2-type response. One study has shown that oral immunization with parasite antigen and CT elicits both serum IgG and mucosal IgA Ab responses (Zhang et al. 1995). This study, which also assessed anti-parasite Abs in bile (where IgA was the predominant isotype), revealed that oral immunization normally induces serum IgA, and in experimental species such as mice, rats, and rabbits, where the serum IgA is predominantly polymeric, the pIgA is transported into the GI tract. Thus, all studies that assess intestinal IgA responses should ensure that the response actually occurs locally and

therefore perform assays to detect IgA-producing plasma cells in lamina propria regions of the GI tract.

Attenuated avirulent salmonella strains have received considerable attention as mucosal vaccine delivery vectors for recombinant proteins associated with virulence (Chatfield et al. 1993; Curtiss et al. 1993; Roberts et al. 1994; Doggett and Brown 1996). After oral administration, *Salmonella* spp. replicate directly in the mucosa-associated tissues (e.g. PP) and thereafter disseminate via the MALT to systemic sites (e.g. spleen). This characteristic dissemination pattern of growth in both mucosal and systemic sites allows *Salmonella* spp. to induce broad-based immune responses, including cell-mediated as well as serum IgG and mucosal S-IgA Ab responses. Although a large number of genes from bacteria, viruses, parasites, and mammals have been expressed in attenuated r*Salmonella* spp. (Curtiss et al. 1993; Roberts et al. 1994), few studies have fully characterized both T- and B-cell responses to the expressed protein Ag. In particular, the balance between Ag-specific $CD4^+$ Th1 and Th2 cells, and their subsequent influence on subclass-specific IgG and mucosal IgA responses, have received little attention in these systems. Such clarity is paramount to the development of delivery protocols that will provide the appropriate immune response to a given pathogen.

A pioneering study in this area showed that mice given an oral attenuated *S. typhimurium* (expressing leishmania surface protein gp63) elicited $CD4^+$ T cells that produced IFN-γ and IL-2, but not IL-4 (Yang et al. 1990). The results at first might appear puzzling. As it appears that mucosal S-IgA responses are dependent on Th2 cells and cytokines such as IL-5, IL-6, and IL-10, by what mechanisms do these attenuated r*Salmonella*-expressing foreign protein antigens induce S-IgA responses? Recent studies have addressed this issue by use of r*Salmonella* spp. expressing the *Tox C* gene of TT. Oral administration of r*Salmonella Tox C* resulted in predominant serum IgG2a and IgG2b anti-TT as well as mucosal S-IgA anti-TT Ab responses (VanCott et al. 1996) (Figure 12). Further, splenic and PP $CD4^+$ T cells selectively produced IFN-γ and IL-2 as well as the Th2-cytokine IL-10 (VanCott et al. 1996). Also, Mϕs from these mice produced heightened levels of IL-6 (VanCott et al. 1996) (Figure 12). Clear verification that IL-4 is not involved was shown by oral immunization of IL-4 knockout ($IL\text{-}4^{-/-}$) mice which produced serum IgG2a and mucosal S-IgA Abs. Interestingly, $CD4^+$ T cells in these mice exhibited two cytokine patterns, a Th1-phenotype as well as T cells that produced IL-6 and IL-10, but not IL-5 (Okahashi et al. 1996) (see Figure 11). The latter subset of Th2 cells, which produce only IgA-enhancing cytokines, has been termed 'level 2 Th2-type cells' in contrast to so-called 'level 1 Th2-type cells' producing an array of IL-4, IL-5, IL-6, and IL-10.

NASAL IMMUNIZATION

Nasal antigen plus mucosal adjuvant delivery has emerged as perhaps the most effective route for induction of both peripheral and mucosal immunity. Again, most studies can be divided into those that use soluble vaccine components with mucosal adjuvants such as CT

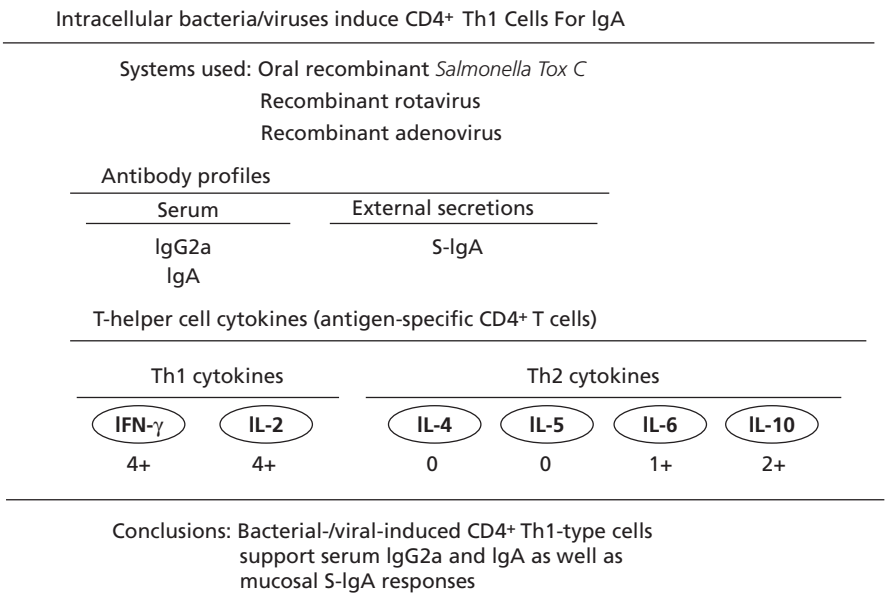

Figure 12 *T-helper 1 (Th1) cells for IgA responses: induction of S-IgA Abs via Th1-type responses. Oral administration of recombinant* Salmonella Tox C *resulted in predominant serum IgG2a and IgG2b anti-tetanus toxin (TT) as well as mucosal S-IgA anti-TT Ab responses. Further, splenic and Peyer's patch $CD4^+$ T cells selectively produced interferon-γ and interleukin-2 as well as the Th2 cytokine interleukin-10.*

(as well as protein–CT-B conjugates) versus studies with attenuated vectors. A series of extensive studies using the influenza virus model demonstrated that nasal immunization with influenza vaccine provides more effective protective immunity than oral immunization (Hirabayashi et al. 1990; Tamura and Kurata 1996). Nasal immunization with trivalent influenza vaccines in the presence of CT-B containing a trace amount of A subunit provides cross-protection against a broad range of viruses (Tamura et al. 1992). It was also shown that nasal immunization with influenza vaccine together with LT-B (containing a trace amount of the LT) induces antigen-specific immune responses in humans (Hashigucci et al. 1996). These findings show that an appropriate nasal vaccine can provide effective immunity against viral infection.

With regard to vectors, most studies have been limited to respiratory tract viral pathogens, which have been subjected to attenuating mutations or genomic deletions. It is interesting that recombinant adenoviruses (r-Ad), currently used for gene therapy, are also candidates for mucosal delivery of vaccine proteins. In most current protocols, vaccine is instilled into each nostril (usually 10 μg/nostril) and inhaled, resulting in effective delivery of vaccine presumably into NALT. Larger aliquots are subsequently swallowed, resulting in oral immunization. For this reason, any nasal protocol cannot avoid some oral delivery, although most studies of oral immunization employ gastric intubation to avoid potential nasal immunization. It should also be noted that two routes of pulmonary immunization have been used: intratracheal delivery versus nasal instillation. In general, it appears that intratracheal immunization tends to induce responses in the lower lungs and associated cervical and other draining lymph nodes, whereas nasal immunization sensitizes NALT and associated cervical lymph nodes.

Several studies can be used to illustrate principles associated with nasal immunization. In one, nasal administration of inactivated RSV with CT resulted in nasal IgA and serum IgG anti-RSV responses (Reuman et al. 1991). Analysis of IgG subclasses suggests that both IgG1 and IgG2a are induced (Reuman et al. 1991). Interestingly, infection with RSV and subsequent Th1-type responses are characterized by a favorable outcome, whereas Th2-type responses are associated with significant pathology (Graham et al. 1991a, b). Nasal immunization with the C fragment of TT (fragment C) and CT as adjuvant resulted in serum antibody responses characterized by comparable IgG1, IgG2a, and IgG2b anti-fragment C titers, suggesting that the use of CT as an adjuvant with fragment C induces a response characterized by both Th1- and Th2-type responses (Roberts et al. 1995). However, when fragment C is administered nasally with pertussis toxin (PT) or a mutated form of PT known as PT-9K/129G as mucosal adjuvants, anti-fragment C IgG1 predominates, suggesting that an immune response biased toward the Th2-type has been induced (Roberts et al. 1995). Direct comparisons between CT and PT or PT-9K/129 in this study are difficult because the use of CT is associated with much more potent anti-fragment C IgG responses. Further investigation will be needed to determine the role that adjuvants, the vaccine antigen, and the route of immunization play in induction of $CD4^+$ Th1- and Th2-type responses.

Mutants of CT constructed by substitution of serine with phenylalanine at position 61 (mCT-S61F) and glutamate by lysine at position 112 (mCT-E112K) in the ADP-ribosyltransferase activity center of the CT gene from *Vibrio cholerae* 01 strain GP14 display no ADP-ribosyltransferase activity or enterotoxicity (Yamamoto et al. 1997b). These mutants have been studied as potential nasal adjuvants. The levels of antigen-specific serum IgG and S-IgA Abs induced by the mutants are comparable to those induced by wild-type CT and significantly higher than those induced by recombinant CT-B (Yamamoto et al. 1997a, b). Further, the mCT-E112K, like mCT, induces Th2-type responses through a preferential inhibition of Th1-type $CD4^+$ T cells. Mutations in other sites of the CT molecule were reported to induce nontoxic derivatives but the adjuvant activity was also affected.

Mutant LT molecules, whether possessing a residual ADP-ribosyltransferase activity (e.g. LT-72R) or totally devoid of it (e.g. LT-7K and LT-6K3), can function as mucosal adjuvants when intranasally administered to mice together with unrelated antigens (Rappuoli et al. 1999). However, discrepant results were reported when two nontoxic mLTs were tested for their adjuvanticity after oral immunization of mice. Thus, although mutant LT-E112K (bearing a substitution in the active site of the A subunit) was unable to amplify the response to keyhole limpet hemocyanin when both were given orally to C57BL/6 mice, the mutant with a substitution in the protease-sensitive region, LT-R192G, retained the ability to act as a mucosal adjuvant (Dickinson and Clements 1995). Whether the type of the substitution played a role in the reported discrepancies remains to be elucidated. As LT induces a mixed $CD4^+$ Th1-type (i.e. IFN-γ) and Th2-type (i.e. IL-4, IL-5, IL-6, and IL-10) response (Takahashi et al. 1996), one might envision the use of mutants of LT when both Th1- and Th2-type responses are desired.

MUCOSALLY-INDUCED TOLERANCE

Mucosal tolerance

In addition to the beneficial induction of Ag-specific S-IgA and serum IgG Ab responses after mucosal immunization, the mucosal route of Ag delivery can also induce another type of immune response, namely the induction of systemic unresponsiveness (e.g. oral tolerance). Thus, mucosal Ag delivery can either up- or down-regulate

systemic immune responses. As discussed above, for the purpose of mucosal vaccine development against infectious diseases, the goal is induction of both mucosal and systemic immunity in order to provide two layers of protection. In contrast, inhibition of Ag-specific immune responses in systemic compartments by mucosal Ag delivery is important for the prevention of over-stimulation of responses and frequently encountered hypersensitivity responses to food proteins and allergens. Further, this system could potentially be applied to the prevention and possibly the treatment of autoimmune diseases by feeding relevant Ags.

Oral administration of a single high-dose or repeated oral delivery of low doses of proteins have been shown to induce systemic unresponsiveness, presumably in the presence of mucosal IgA Ab responses (Challacombe and Tomasi 1980; Tomasi 1980; Mowat 1987; Weiner et al. 1994; Czerkinsky et al. 1999; Garside et al. 1999; Mayer 2000; Fujihashi et al. 2001a) (Figure 13). These immunologically distinct responses in mucosa-associated versus systemic-associated lymphoid tissues were originally termed oral tolerance (Tomasi 1980). More recent studies have shown that the nasal administration of proteins also induces systemic unresponsiveness (Hoyne et al. 1993; McMenamin and Holt 1993; Metzler and Wraith 1993; Tian et al. 1996; Higuchi et al. 2000) and has led to the more general term 'mucosal tolerance' to include nasal or oral Ag induction of unresponsiveness.

Mucosal administration of protein Ag is a long-recognized method of inducing peripheral unresponsiveness or tolerance (Wells 1911). This is a unique immune reaction and is characterized by the fact that experimental animals fed large quantities of protein Ag become refractory or have a diminished capability to develop an immune response when re-exposed to that same Ag introduced by the systemic route (e.g. by parenteral injection) (Tomasi 1980; Mowat 1994). This unique response is an important natural physiological mechanism whereby the host presumably avoids development of hypersensitivity reactions to many ingested food proteins and other antigens (Garside et al. 1999). Thus, tolerance (or systemic unresponsiveness) represents the most common response of the host to our environment. The continuous ingestion of several thousand different food proteins is but one important example, whereas tolerance to our indigenous microflora that colonize the large intestine represents another major example. It is also useful to consider that induction of mucosal and systemic immunity by oral immunization is rather difficult and requires use of potent mucosal adjuvants, vectors, or other special delivery systems (see previous section). Further, the development of mucosal tolerance against pollen and dust antigens could also be essential for the inhibition of allergic reactions, including IgE-mediated hypersensitivity.

Most now agree that mucosal tolerance is mediated by T cells which are involved in the generation of active suppression or clonal anergy and/or deletion (Friedman and Weiner 1994), e.g. high doses of antigen given by the oral route induced clonal deletion or anergy (Whitacre et al. 1991; Melamed and Friedman 1993; Chen et al. 1995b) characterized by the absence of T-cell proliferation and diminished IL-2 production, as well as IL-2R expression. Frequently administered, low doses of antigen, however, induced active suppression by $CD4^+$ or $CD8^+$ T cells, which secreted cytokines such as

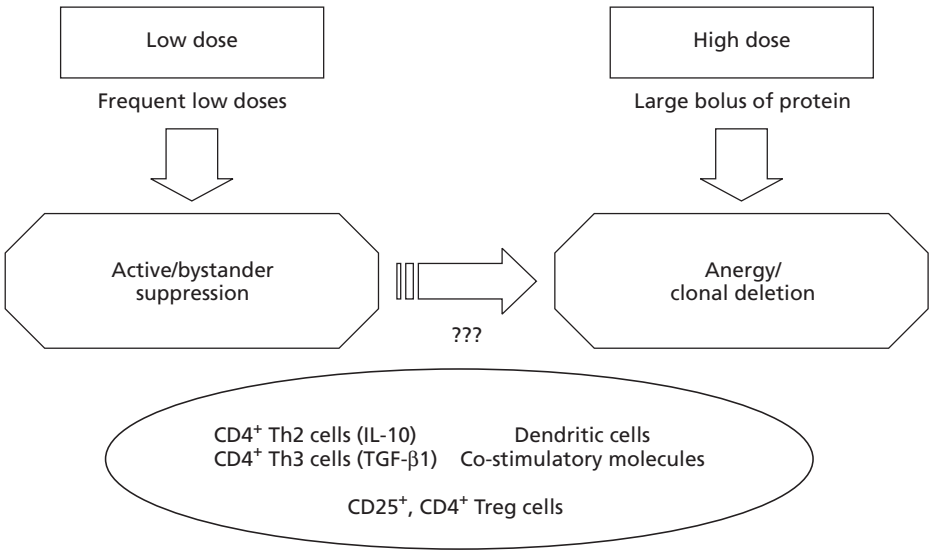

Figure 13 *Proposed mechanisms for mucosal tolerance: oral administration of a single high-dose or repeated oral delivery of low doses of proteins have been shown to induce systemic unresponsiveness. High doses of antigen given by the oral route induced clonal deletion or anergy characterized by the absence of T-cell proliferation and diminished interleukin 2 (IL-2) production as well as IL-2 receptor expression. Frequently administered low doses of antigen induced active suppression by $CD4^+$ or $CD8^+$ T cells which secreted cytokines such as transforming growth factor-β, and IL-10.*

TGF-β, IL-4, and IL-10 (Khoury et al. 1992; Chen et al. 1995a) (Figure 13). It is interesting to note that the latter scenario involves cytokines that are also known to upregulate IgA production (Czerkinsky and Holmgren 1995) and is thus compatible with the observation that mucosal immune responses and systemic tolerance may develop concomitantly (Asano et al. 1995; McGhee et al. 1999). As oral tolerance is specific for the antigen initially ingested or inhaled, and thus does not influence the development of systemic immune responses against other antigens, its manipulation has become an increasingly attractive strategy for preventing and possibly treating illnesses associated with or resulting from the development of untoward immunological reactions against specific antigens encountered or expressed (autoantigens) in nonmucosal tissues.

Mechanisms to explain oral tolerance

In the late 1970s and early 1980s, mucosal immunologists had already made attempts to investigate the possible mechanisms of oral tolerance at a time when the immune system was not characterized at the cellular and molecular levels (Thomas and Parrott 1974). Although several possible mechanisms (e.g. B-cell tolerance, anti-idiotypic antibody, intestinal antigen-processing events for tolerogen, and APCs) have been shown to be involved in the induction of oral tolerance (Mowat 1994), the most compelling evidence to date suggests that T cells are the major cell type involved in the induction of mucosally induced tolerance. In earlier work, it was shown that systemic unresponsiveness was induced by the adoptive transfer of T cells from rats orally fed bovine serum albumin (Thomas and Parrott 1974). Subsequently, a large number of studies demonstrated that oral immunization of protein antigen induces $CD4^+$ Th cells in mucosa-associated tissues that support IgA responses, whereas suppressor T cells were induced in systemic compartments such as spleen that downregulate Ag-specific IgM, IgG, and IgE responses (Mattingly and Waksman 1978; Ngan and Kind 1978; Kagnoff 1980; Kiyono et al. 1980, 1982b; Richman et al. 1981; Mowat et al. 1988), e.g. oral feeding of ovalbumin to mice led to the generation of Th cells supporting IgA responses and suppressor T cells for IgG and IgE responses in GALT (Mattingly and Waksman 1978; Ngan and Kind 1978; Mowat et al. 1988). Further, the former T cells for IgA responses remained in Peyer's patch, whereas the suppressor T cells migrated into the systemic compartment (e.g. spleen). These observations were considered to be logical explanations for cellular mechanisms of oral tolerance where Peyer's patch-derived $CD4^+$ Th cells supported IgA responses, whereas splenic T-suppressor cells induced systemic unresponsiveness. This must now be re-evaluated, because it has been shown that administration of a large dose of ovalbumin to mice followed by attempts at oral immunization with ovalbumin plus CT resulted in unresponsiveness in both mucosal and peripheral immune compartments (Kato et al. 2001).

A role for αβ T cells in oral tolerance

The αβ TCR^+ T cells appear to be the major players in downregulation of systemic immune responses to orally administered antigens. Most also agree that the status of oral tolerance can be explained by (1) clonal anergy, (2) clonal deletion of T cells, or (3) active suppression by T-regulatory (Treg) cells through the secretion of inhibitory cytokines (Whitacre et al. 1991; Miller et al. 1992; Gregerson et al. 1993; Melamed and Friedman 1993, 1994; Friedman and Weiner 1994; Garside et al. 1995; Hirahara et al. 1995). Low doses of oral antigen tend to favor the latter form of inhibition, whereas higher doses of feeding induce clonal anergy of immunocompetent T cells (Gregerson et al. 1993; Friedman and Weiner 1994; Garside et al. 1995; Hirahara et al. 1995). These two forms of oral tolerance are not mutually exclusive and may occur simultaneously after oral administration of antigens.

T-CELL ANERGY

Anergy is defined as a state of T-cell unresponsiveness characterized by the lack of proliferation and IL-2 synthesis, and by diminished IL-2R expression (Schwartz 1990), a condition reversed by pre-culturing T cells with IL-2 (DeSilva et al. 1991). Oral tolerance to a large dose of ovalbumin Ag-induced anergy in ovalbumin-specific T cells (Melamed and Friedman 1993) (see Figure 13). Further, oral myelin basic protein (MBP) diminished IL-2 and IFN-γ synthesis (Whitacre et al. 1991). These findings suggest that Th1-type T cells may be susceptible to the induction of anergy after oral feeding. To support this, it has been shown that Th1-type cells appear to be more sensitive to the induction of tolerance in vitro than Th2-type cells (Williams et al. 1990). In vivo evidence has demonstrated that Th1 cells are likely to be anergized in oral tolerance (Burstein and Abbas 1993). This may be an oversimplification because it has been shown that oral tolerance can be induced in mice defective in Th1 ($STAT4^{-/-}$) or Th2 ($STAT6^{-/-}$) cells (Shi et al. 1999). Further, in order to identify which lymphocyte compartment (e.g. $CD4^+$ versus $CD8^+$ T cells) preferentially mediates the induction of oral tolerance, cell transfer experiments were recently performed using severe combined immunodeficiency (SCID) and *nu/nu* mice (Hirahara et al. 1995). Adoptive transfer of splenic lymphocytes from mice orally tolerized with bovine α-casein resulted in the induction of tolerance in these immunocompromised mice. It was shown that oral tolerance was induced by anergized $CD4^+$ but not $CD8^+$ T cells. Taken together, a form of oral tolerance can be achieved by the induction of anergic $CD4^+$ T cells in the systemic compartment.

AN IMBALANCED TH1/TH2 CYTOKINE NETWORK

The induction of oral tolerance can also be explained by dysregulation of homeostasis between Th1- and Th2-type cells, e.g. preferential activation of Th2 cells may lead to downregulation of Th1 CMI responses by Th2 cytokines such as IL-4 and IL-10 (Burstein and Abbas 1993). In addition, Th1-type cells are much more sensitive to anergy induction after oral administration of protein antigens. These findings suggest that oral tolerance is associated with selective downregulation of Th1 cells by Th2 cells via their respective cytokines in the systemic immune compartment. This possibility is consistent with the fact that oral tolerance has more profound effects on Th1-regulated CMI responses than on Th2-mediated antibody responses. However, recent studies have shown that feeding high doses of ovalbumin inhibited production of both Th1 (IL-2 and IFN-γ) and Th2 (IL-4, IL-5, and IL-10) cytokines and resulted in the reduction of IFN-γ- and IL-4-dependent antigen-specific IgG2a and IgG1 Ab responses, respectively (Garside et al. 1995). These findings indicate that both subsets of Th cells are involved in the induction of oral tolerance and both are downregulated. Oral ovalbumin induced brisk IFN-γ production with inhibition of the IgG-enhancing cytokine IL-4 by Th2 cells, leading to reduced B-cell responses, although no oral tolerance was seen in IFN-γ knockout mice (Kweon et al. 1998). Further, repeated oral administration of high doses of ovalbumin to ovalbumin-specific TCR Tg mice resulted in an IFN-γ-dominated immune responses in the Peyer's patches (Marth et al. 1996). Taken together, the immunological consequences of systemic B-cell tolerance induced by a high dose of oral Ag could be the result of IFN-γ-mediated immune regulation, with significant suppression of Th2-type cells.

T-regulatory cells in oral tolerance

The finding that $CD4^+$ T-cell clones were generated after induction of oral tolerance to MBP clearly led to the description of a new phenotype of regulatory T cells. Clones of $CD4^+$ T cells were MBP specific and, of 48 clones assessed, 42 produced the active form of TGF-β1. Six clones produced high levels of TGF-β1 with essentially no IL-4 or IL-10 (Chen et al. 1994). On the other hand, five clones produced high IL-4 and IL-10, which is of course typical of Th2-type cells. The authors suggested the existence of a TGF-β1-producing, regulatory T cell involved in control of mucosal immune responses and named it Th3 (Chen et al. 1994).

The Treg cells appear to control mucosal immunity, tolerance, and inflammation to a higher degree than comparable Treg cell types in peripheral lymphoid tissues. Generally speaking, Treg cells do not proliferate well in vitro, a characteristic reminiscent of anergic T cells. In fact, cloned anergic T cells can suppress immune response in vivo and this appears to be partly caused by effects on APCs (Taams et al. 1998; Chai et al. 1999; Vendetti et al. 2000). Thus, anergic T cells downregulate DC expression of CD80 and CD86 in a contact-specific fashion (Vendetti et al. 2000). Further, anergic T cells have been shown to produce IL-10, which is a major characteristic of some $CD4^+$ $CD25^+$ Treg cells (Sundstedt et al. 1997; Buer et al. 1998; Sakaguchi 2000; Shevach 2000). Thus, it appears that anergic T cells, through production of IL-10 (and perhaps through other mechanisms), become Treg cells that suppress immune responses to other antigens (Buer et al. 1998), a process sometimes termed 'infectious tolerance' or 'bystander suppression'. Despite their poor proliferative responses to Ag, it has been possible to induce populations of T-cell clones after incubation with IL-10 and alloantigen in humans (Groux et al. 1996) or to ovalbumin peptide in DO11.10 mice (Groux et al. 1997). The T-cell clones obtained had similar properties, including secretion of high levels of IL-10, some production TGF-β1, with no IL-4 synthesis and poor proliferative responses (Maloy and Powrie 2001). Cells with these characteristics are now termed T-regulatory one cells (Tr1). Thus far, Tr1 and Th3 cells have in common the production of TGF-β1 (Th3) or TGF-β1 + IL-10 (Tr1) with suppressive-type properties.

In a hapten-induced model of colitis, it was shown that 2,4,6-trinitrobenzene sulfonic acid (TNBS) coupled to mouse colonic (self) proteins, when given orally, led to oral tolerance to hapten and a failure to induce TNBS colitis (Neurath et al. 1996). Interestingly, both Peyer's patch and lamina propria $CD4^+$ T cells, when stimulated via the TCR, produced high levels of TGF-β1, IL-4, and IL-10, suggesting that Th3 and possibly Tr1 cells regulate this type of tolerance (Neurath et al. 1996). Direct evidence for intestinal tolerance to luminal bacteria in humans was provided by the finding that lamina propria $CD4^+$ T cells responded poorly to *E. coli* proteins, a condition reversed by anti-IL-10 or anti-TGF-β1 mAb treatment (Khoo et al. 1997). The best direct evidence for induction of $CD4^+$ $CD25^+$ Treg cells by oral Ag was provided by an adoptive transfer model of DO11.10 TCR ovalbumin Tg T cells. Transfer followed by either intravenous or oral ovalbumin led to an increase in ovalbumin-specific, $CD4^+$ $CD25^+$ T cells (Thorstenson and Khoruts 2001). It should be emphasized that this last study used 25 mg ovalbumin in drinking water over an 18-h period, suggesting a relatively high oral dose of Ag-induced Treg cells (Thorstenson and Khoruts 2001).

A distinct role for γδ T cells in low-dose oral tolerance

It is well established that mucosal immune compartments such as the intestinal epithelium contain large

numbers of γδ T cells in addition to αβ T cells, as does the lamina propria region of the small intestine (Aicher et al. 1992). As γδ T cells are localized in mucosa-associated tissues, we hypothesized that mucosal γδ T cells could be involved in immune responses in the lamina propria of normal mice, e.g. IEL T cells from mice immunized orally with sheep erythrocytes (SRBC) were separated into γδ and αβ T cells. When purified γδ and αβ T cells were adoptively transferred to mice orally tolerized with SRBCs, a conversion of systemic unresponsiveness to IgM, IgG, and IgA anti-SRBC Ab responses was achieved in mice that received γδ but not αβ T cells (Fujihashi et al. 1992). A more recent study has also demonstrated that γδ T cells isolated from mucosa-associated tissues of mice immunized orally with protein vaccine (B subunit of LT from *E. coli* – LT-B) exhibited a similar activity, i.e. IEL γδ T cells from LT-B-fed mice (which were tolerized) abrogated systemic unresponsiveness after adoptive transfer to syngenic mice orally tolerized with LT-B (Takahashi et al. 1995). Thus, γδ T cells appear to be important in the maintenance of mucosal IgA responses and possibly systemic unresponsiveness. In this regard, studies demonstrated that γδ T cells are essential for the induction of oral tolerance using mAb anti-γδ TCR-treated and TCR$\delta^{-/-}$ mice (Ke et al. 1997). Further, a distinct role was suggested for γδ T cells in the induction of high- versus low-dose oral tolerance. Although γδ T cells play a major immunoregulatory role for the induction of low-dose oral tolerance via upregulation of IL-10 synthesis, this T-cell subset is not involved in high-dose oral tolerance (Fujihashi et al. 1999) (see Figure 13).

A role for Peyer's patches in oral tolerance

The precise site of Ag uptake in the GIT during oral tolerance induction has not been firmly established. At least three possibilities could be proposed and none is mutually exclusive (Rubas and Grass 1991). First, Ag may be pinocytosed into the epithelial cells themselves and interactions with IELs may influence oral tolerance. Second, Ag may selectively enter the GALT via M cells and lead to APC–T-cell interactions which downregulate T-/B-cell responses. Finally, oral Ag may not perturb the GIT immune system at all, but simply enter and cross the epithelium in a paracellular fashion and reach the bloodstream, where tolerance would be induced. Some investigators have suggested that organized lymphoid tissue in the GIT was not required for oral tolerance to ovalbumin, because B-cell-defective mice, which contain poorly developed Peyer's patches, were fully tolerized at the level of T cells (Alpan et al. 2001). Although the study claimed that GALT was absent, others have shown that some remnants of Peyer's patches are seen in μMT mice (Golovkina et al. 1999). Others have also shown that direct injection of Peyer's patches induced oral tolerance (Chen et al. 2000). The availability of mice without Peyer's patches has allowed reinvestigation of the notion that GALT may be involved in oral tolerance (Figure 14). In one study, it was shown that mice lacking GALT but retaining mesenteric lymph nodes (MLN) could be orally tolerized to ovalbumin (Spahn et al. 2001). In other studies, mice lacking Peyer's patches but retaining MLNs were found to be resistant to oral tolerance to protein (Fujihashi et al. 2001b); however, these mice showed normal mucosal S-IgA Ab responses to oral protein given with CT as adjuvant (Yamamoto et al. 2000). One cannot yet conclude whether GALT is a strict requirement for oral tolerance to proteins.

Oral tolerance in humans

Increasing attention is being paid to oral tolerance and the role that it could play in the prevention or treatment of autoimmune diseases, including multiple sclerosis, rheumatoid arthritis, and uveitis, as well as type 1 diabetes and contact hypersensitivity (Weiner 1997). Indeed, humans fed the neoantigen KLH developed systemic unresponsiveness evaluated by delayed-type hypersensitivity and T-cell proliferative responses (Husby et al. 1994). However, B-cell responses were primed in both systemic and mucosal sites (Husby et al. 1994). In more recent studies, humans naturally ingesting the dietary Ags bovine γ-globulin, ovalbumin, and soybean protein developed a T-cell tolerance characterized by anergy (Zivny et al. 2001). Antigen-specific Th3 cells secreting TGF-β have been observed in the blood of multiple sclerosis patients orally treated with a bovine myelin preparation (Fukaura et al. 1996), demonstrating that oral administration of autoantigen can induce autoantigen-specific TGF-β-secreting cells in a human autoimmune disease.

Pilot clinical trials of oral tolerance have been conducted in patients with autoimmune diseases and promising clinical benefits have been reported (Weiner 1997; Czerkinsky et al. 1999). Despite encouraging results that have been reported regarding oral delivery of autoantigens for the prevention and treatment of autoimmune diseases, a follow-up study provides an unfortunate alternative possibility. Oral feeding of autoantigen in mice resulted in the generation of antigen-specific $CD8^+$ CTL responses, which could lead to the aggravation of autoimmune disease (Blanas et al. 1996). Thus, one must also keep in mind that oral administration of autoantigen may induce undesirable $CD8^+$ CTLs that may worsen the disease instead of preventing the development of autoimmune diseases.

Oral desensitization to nickel allergy was reported to reduce nickel-specific T cells and the cutaneous form of eczema (Bagot 1995). Oral Ags had earlier been

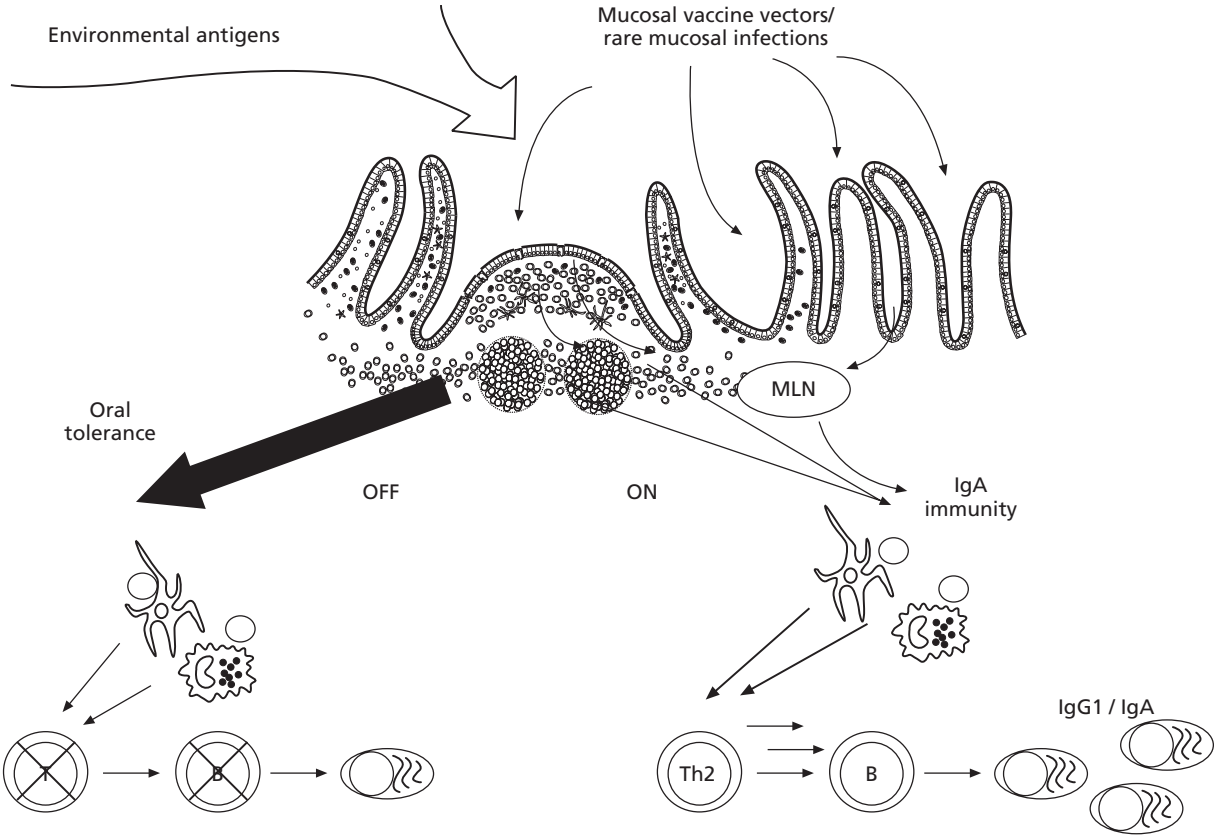

Figure 14 *Regulation of mucosal immunity and tolerance: mucosal homeostasis provided by mechanisms of tolerance including oral tolerance may be common and important mucosal immune responses. On the other hand, induction of vaccine-specific IgA responses at mucosal surfaces requires mucosal adjuvants or delivery systems.*

proposed to prevent or even treat allergic reactions to common allergens such as house-dust mite and grass pollens (Wortmann 1977; Rebien et al. 1982). However, this has not yet reached fruition. Thus, the experience of most investigators is that, once an immune response has been induced, it cannot be reversed through mucosal tolerance. Although the above examples indicate that oral tolerance offers promise for inducing antigen-specific immunological tolerance, its therapeutic potential remains limited by practical problems. Indeed, large quantities of orally administered antigens (e.g. milligrams in mice, grams in humans) are required to induce systemic unresponsiveness in experimental animals and humans. Taken together, these initial human trials have shown that oral tolerance, which paralleled results in animal models, could be induced in humans. However, a consistent clinical efficacy remains to be shown in human diseases.

CONCLUSIONS

The mucosal immune system is maintained through well-organized, interactive, innate, and acquired immune compartments. Thus, mucosal surfaces, which cover huge areas, are protected in concert by the two arms of this defense system, respectively. In addition, most studies clearly suggest that the main players in innate immunity serve as a bridge with acquired immunity, e.g. IECs produce antimicrobial peptides such as defensins. Further, an array of cytokines and chemokines is also produced by epithelial cells and these molecular responses subsequently induce expression of MHC I and II as well as co-stimulatory molecules, which are key factors for the APC-directed initiation of acquired mucosal immune responses. In addition, cross-talk by the epithelium to IEL T cells again bridges with acquired immunity. In this regard, IECs and IEL T cells cross-regulate each other in maintaining mucosal homeostasis at the barrier interface.

It is obvious that S-IgA Abs play central roles in mucosal immunity. Thus, large efforts have been made to define how S-IgA Ab responses are regulated. The organized mucosal inductive and effector tissues are essential elements and play key roles in the induction and regulation of S-IgA Ab responses. Inside these tissues, $CD4^+$ T cells and their derived cytokines are essential for B-cell switching to sIgA expression, stimulation, growth, and terminal differentiation into IgA-producing plasma cells. Induction of Ag-specific IgA Ab responses at mucosal surfaces is a rather difficult task

(see Figure 14). In this regard, potent mucosal adjuvants or former pathogens, including recombinant delivery systems, are essential for mucosal vaccine development, and have been extensively studied. To date, only mucosal immunization (oral, nasal, and rectal routes) successfully induces S-IgA Ab responses. Effective mucosal vaccines provide two layers of defense, the first at mucosal surfaces (S-IgA) and the second in systemic lymphoid sites (plasma IgG). The occurrence of Ag-specific S-IgA Ab responses is a relatively rare type of immune response. Thus, mucosal homeostasis provided by mechanisms of tolerance including oral tolerance may be a more common and important type of mucosal immune response (see Figure 14). In summary, the major goals in the past, the present and the future will be to elucidate the cellular and molecular mechanisms involved in the induction and regulation of opposite types of mucosal immune responses, i.e. S-IgA immunity and mucosal tolerance (see Figure 14).

'Superantigens' is the designation for a heterogeneous group of proteins that use a common, extremely efficient mechanism of T-lymphocyte stimulation. They bind to MHC class II molecules on antigen-presenting cells and to variable parts of the T-cell receptor on $CD4^+$ and $CD8^+$ T cells, thus mimicking the recognition of specific antigen. The prototype superantigen is the staphylococcal enterotoxin B, member of a family of genetically related pyrogenic exotoxins produced by *Staphylococcus aureus* and *Streptococcus pyogenes*. This principle of T-lymphocyte stimulation has been evolved several times independently by infectious pathogens.

The unusual mechanism of T-lymphocyte stimulation has been explored at a molecular level and it has been shown that the pathogenic effects of these molecules are the result of their ability to stimulate a large fraction of T cells. Consequences of confrontation of the body with superantigenic toxins are:

1. shock, mediated by a massive liberation of cytokines from cells of the immune system;
2. immunosuppression, mainly caused by an uncoordinated activation of the immune system and a massive deletion of T cells;
3. autoimmunity resulting from bypass activation of autoreactive T and B cells.

INTRODUCTION

Antigen recognition by T lymphocytes is one of the most sensitive assays in biology. With its antigen receptor the T cell can respond to only a few antigenic peptides presented by an antigen-presenting cell (APC). This unique sensitivity is provided by a set of molecular mechanisms that intracellularly amplify the initial signal given by one or only a few T-cell receptors (TCR). Superantigens have been adapted in evolution to use the T-cell machinery to become most effective T-cell stimulators. Although there are different types of superantigens that have been independently generated several times in evolution and that are completely unrelated to each other, they all use the same molecular mechanism: they bind to major histocompatibility complex (MHC) class II molecules on APCs and to the TCR, and thus crosslink the TCR to the MHC molecule of the APC. Therefore, by closely mimicking antigen recognition they use most of the amplification mechanisms that the T cell uses normally. Thus, a hallmark of all superantigens is their enormous potency: they are active in concentrations of 10^{-9} mol/l. This means that a few picograms per milliliter can still effectively stimulate T cells in culture. Another characteristic feature of superantigens is their use of variable determinants on molecules of the immune system: all superantigens known so far bind to the variable part of the TCR β chain (Vβ); thus each superantigen stimulates a particular fraction (up to 30 percent) of the T-cell repertoire. On the MHCII molecule there are different binding sites used by different superantigens, some superantigens even involve the antigenic peptide in their binding.

This principle of T-lymphocyte stimulation has evolved several times independently. Infectious pathogens as different as gram-positive cocci, gram-negative rods, a mycoplasma, and retroviruses produce superantigens that are apparently completely unrelated to each other. Obviously, this very special mechanism of

T-cell stimulation has been developed by very different pathogens independently in evolution so it is likely that additional pathogens will also use it. Therefore, in the last few years, there have been a surprisingly large number of reports describing novel superantigens in various viruses, bacteria, or protozoa. With one exception, the lectin *Urtica dioica* agglutinin of the stinging nettle (Saul et al. 2000), all molecules that have been proposed to be superantigens are produced by infectious pathogens. (The lectin has two saccharide-binding sites and its superantigenic properties arise from the simultaneous fixation of glycans on the TCR and MHC molecules.) The long list of candidate superantigens includes a wide range of bacteria, protozoa, and viruses, some of which are listed in Table 1. In most cases the evidence is still indirect or the initial report has not been confirmed by an independent study. This review limits the discussion to those superantigens that are beyond any doubt superantigens.

PYROGENIC EXOTOXINS OF *STAPHYLOCOCCUS AUREUS* AND *STREPTOCOCCUS PYOGENES*

Genes and molecules

The pyrogenic exotoxins (PET) produced by these two genera of gram-positive cocci comprise a highly polymorphic family of genetically related toxins consisting of the staphylococcal enterotoxins (SE) and the toxic shock syndrome toxin-1 (TSST-1) produced by *Staphylococcus aureus* and streptococcal pyrogenic exotoxins (SPE) produced by *S. pyogenes*. *S. aureus* is widespread among humans and animals and many of these toxins are also present in *S. aureus* strains from other species. They are heat-stable and protease-resistant molecules of molecular mass 22–28 kDa.

Historically, the staphylococcal enterotoxins were defined by their ability to cause emesis and diarrhea in humans and monkeys. They are a major cause of food poisoning worldwide. Initially, five major serotypes SEA, SEB, SEC, SED, and SEE have been described that were serologically defined by the lack of cross-reaction of specific antisera. TSST-1 was initially designated SEF, but was later renamed TSST-1 because of its association with toxic shock syndrome – and because the initial finding of emetic activity could not be confirmed (Reiser et al. 1983). Currently the staphylococcal enterotoxins include in addition SEG, SEH, SEI, SEJ, SEK, SEL, SEM, SEN, SEO, and SEP (Jarraud et al. 2001; McCormick et al. 2001).

The SPEs are usually discussed separately from the SEs because they are derived from another genus and an enterotoxic activity has not been described. However, as such activity can be detected only in humans or monkeys it is not clear whether this putative difference has been sufficiently investigated. From a genetic point of view the separation of the SPEs from the SEs is not appropriate because some SPEs are more related to SEs than to other

Table 2 *Grouping of members of the staphylococcal enterotoxin superfamily according to genetic relatedness (Proft et al. 1999; McCormick et al. 2001)*

Group	Members		Common properties
I	TSST-1	TSST-1 and variants	
II	SEB-like	SEB, $SEC_{(n)}$, SSA, SPEA, SEG	Central cysteine loop
III	SEA-like	SEA, SEE, SEJ, SED, SEH	Central cysteine loop, zinc-binding site
IV	SPEC-like	SPEC, SPEJ, SMEZ, SPEG	Zinc-binding site
V	SPEH-like	SEK, SPEH, SEP, SEI, SEL	Zinc-binding site

Not yet classified: SEM, SEN, SEO (Jarraud et al. 2001).

SPEs. The members of the SE family can be divided into five subgroups (Table 2) according to their sequence relatedness (Betley et al. 1992; Munson et al. 1998; Proft et al. 1999, 2001; McCormick et al. 2001).

Homologies vary considerably within the groups. A common feature of all PETs is the overall molecular architecture: globular two-domain proteins of about 22–29 kDa with a long solvent accessible α-helix in the center of the molecule. Although some PETs, such as TSST-1 or SPEC, share little similarity with any other PET, there is sufficient sequence homology among all PETs to suggest that streptococcal and staphylococcal PETs have evolved from a single ancestor gene. This is in line with the finding that staphylococcal and streptococcal toxins are mixed within the different subgroups. Moreover, as other 'accessory proteins' are not required for bacterial growth many of the PETs are encoded on mobile genetic elements – those for SEA, SEE, SPEA, and SPEC are carried within bacteriophage DNA and for SED and SEJ on plasmid DNA (Betley et al. 1992; Johnson and Schlievert 1984; Weeks and Ferretti 1984; Goshorn and Schlievert 1989). Others are encoded within pathogenicity islands on the chromosome, e.g. TSST-1, SEB, or SEC (Novick et al. 2001). The streptococcal superantigen SSA is more related to SEB and SEC than to other streptococcal PETs, suggesting an intergeneric transfer in that it appears to have been acquired by several different clonal lineages of *S. pyogenes* during the twentieth century (Reda et al. 1994).

A characteristic feature of SEs and SPEs is their extensive polymorphism; there are many alleles of some toxins known which differ in only few amino acids, e.g. three subtypes of SEC have been numbered (SEC1–3) and a number of variants of SEC of *S. aureus* strains derived from humans, dogs, cattle, and food have been cloned (Marr et al. 1993). The variants differ only in a few amino acids but may differ in their biological activity (Bohach 1997). Several isolates of SEC3 that are serologically indistinguishable differ in several mutations. SEA and SEE have very high homology and show strong serological crossreaction; thus SEE could even be classified as a variant of SEA. TSST-1 produced by *S. aureus* strains associated with humans has a p*I* of 7.0 whereas *S. aureus* isolates from sheep produce the variant TSST-0 with a p*I* of 8.6 (Ho et al. 1989) which differs in only seven amino acids from TSST-1, but differs dramatically in its biological activity (Murray et al. 1994). Four different variants of SPEA have been described (Nelson et al. 1991) and three variants of SSA (Reda et al. 1994).

A particularly interesting toxin is the streptococcal mitogenic exotoxin Z (SMEZ) of *S. pyogenes* (Kamezawa et al. 1997). It forms a polymorphic family with wide allelic variation leading to significant antigenic variation (Proft et al. 1999, 2000). Currently more than 25 alleles have been identified (Proft et al. 1999, 2000; Gerlach et al. 2000). All SMEZ variants are powerful stimulators of human Vβ4 and Vβ8 T cells and significant production of SMEZ occurs in about 70 percent of all *S. pyogenes* isolates. The gene encoding SMEZ is chromosomal and almost invariably present in all group A streptococci, making it the most common of all PET genes. The extensive degree of variation can be taken as evidence that SMEZ provides an advantage to the producing *S. pyogenes* and that new variants arise as a result of the need to escape neutralizing antibodies (Proft et al. 2000). It is interesting and still unexplained, in spite of this variation, that all SMEZ alleles target Vβ4 and Vβ8 T cells. It has been speculated that these T cells may have a special function in host defense against *S. pyogenes* (Proft et al. 2000). This conserved Vβ specificity is in contrast to, for example, SEA and SEE which in spite of having 85 percent amino acid identity vary in their Vβ specificities (Hudson et al. 1993).

The frequency of enterotoxin producers among clinical *S. aureus* isolates has been determined in several studies (Lehn et al. 1995). Depending on the origin of the isolates approximately 40–65 percent of *S. aureus* strains produce a PET. Most commonly SEA is produced (20–25 percent of strains), followed by TSST-1 (13–23 percent), SEB (7–13 percent), SEC (5–9 percent), SED (3–6 percent), and SEE (>1 percent). Five to 8 percent produce two enterotoxins, usually SEA plus TSST-1 or SEA plus SED, which is a much higher frequency than would have been expected from respective individual frequencies. Isolates producing toxins, e.g. SEG, SEH, or SEI are extremely rare. Data about the production of SPEA and SPEC by *S. pyogenes* strains isolated

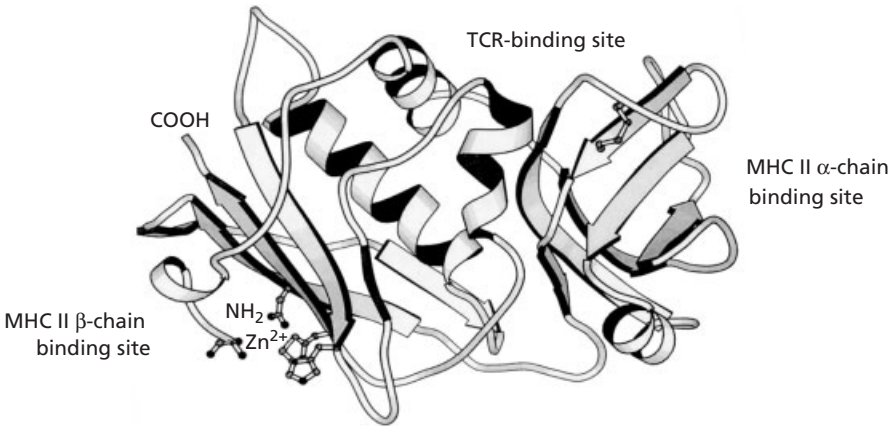

Figure 1 *Polypeptide fold of the staphylococcal enterotoxin A molecule. The binding sites for the T-cell receptor TCR Vβ, for the MHCII α chain and the Zn^{2+}-dependent binding site for the MHCII β chain are indicated. The drawing was made according to the published three-dimensional structure of staphylococcal enterotoxin A (Schad et al. 1995).*

from various sources vary considerably, reflecting the variability of clinical sources and the sensitivity of detection, because *S. pyogenes* produces lower amounts of SPE than *S. aureus* of SE. It is remarkable that the *smeZ* and *speG* genes are present in almost all group A streptococci in contrast to the other toxins (Proft et al. 2000). Information about the purification of the natural proteins has been reviewed (Alouf et al. 1991).

For many members of the SE family (the staphylococcal SEA, SEB, SEC2, SED, SEH, and TSST-1, and the streptococcal SPEA, SPEC, SPEH, SMEZ-2, and SSA) crystal structures are now available (Swaminathan et al. 1992; Prasad et al. 1993; Acharya et al. 1994; Papageorgiou et al. 1995; Schad et al. 1995). More recently, the crystal structures of several toxins, e.g. SEB, TSST-1, SEA, complexed with the human MHCII molecule HLA-DR1 have been determined and have – together with a large number of studies using mutated toxins or class II molecules – illustrated the molecular mode of binding of the toxins to the class II molecule (Jardetzky et al. 1994; Kim et al. 1994).

In spite of their low level of overall sequence homology the PETs show a similar overall structure: they are kidney-shaped, tightly packed molecules with a complex tertiary intertwined folding and are composed of two domains both containing β-sheets and α-helical structures (Figure 1). An interdomain groove is the TCR-binding site; distinct MHCII-binding sites have been identified. Each toxin has individual surface features explaining the individual mechanism of action and the low or absent serological crossreactivity between toxins.

Fraser et al. first described, for SEA, that some superantigens bind a Zn^{2+} ion by two histidine residues and an aspartate residue; in the case of SEA residues this was His-187, His-225, and Asp-227. This binding of Zn^{2+} is required for binding to MHCII molecules (Fraser et al. 1992; Abrahmsen et al. 1995; Hudson et al. 1995). A similar Zn^{2+}-binding motif is present in SEC but not in SEB and is apparently not related to functional activities (Bohach 1997).

Molecular mechanism of action

BINDING TO MHC CLASS II MOLECULES

A hallmark of superantigens is their requirement for MHCII molecules on presenting cells for optimal stimulation of T cells (Fleischer and Schrezenmeier 1988), reflected by their binding to MHCII molecules (Fischer et al. 1989; Fleischer et al. 1989; Fraser 1989; Scholl et al. 1989). Binding differs from normal presentation of processed peptide antigen because superantigens bind as unprocessed proteins outside the antigen-binding groove of the class II molecule (Jardetzky et al. 1994; Kim et al. 1994). Fixed MHCII-positive cells present superantigens effectively to T cells (Fleischer and Schrezenmeier 1988). However, although this basic mechanism is shared by all superantigens individual members of the PETs have developed unique modes of interaction with the class II molecule. Most intriguing are the many different strategies that various PETs use to accomplish MHC binding. They exhibit different binding sites and binding mechanisms and, by using two different binding sites or by forming homodimers, they can crosslink MHC molecules.

The staphylococcal enterotoxins and the SPEs SSA and SPEA have a generic binding site for the MHC α chain in their N-terminus. The toxins of groups IV and V as well as SEH appear not to use or possess this binding site, but use a high-affinity binding site for the β chain via zinc.

The crystal structures of the complex between HLA-DR1 and SEB or TSST-1 shows that SEB and TSST-1 bind to overlapping regions on the monomorphic α chain. Both toxins use residues of the N-terminal domain for this interaction. SEB binds at the side of the molecule leaving the peptide binding site and the peptide exposed (Jardetzky et al. 1994). This binding is of low affinity and it has been suggested that, in the trimolecular complex of SEB, class II molecule, and TCR, the TCR will interact with the class II molecule to

stabilize the complex (Seth et al. 1994). TSST-1, in contrast, binds on the top of the α chain and covers the α chain α-helix peptide-binding site (Kim et al. 1994). Binding to the class II molecule does not change the conformation of TSST-1 (Mitchell et al. 1997). Although the binding sites of SEB and TSST-1 overlap on the class II molecule the two toxins do not compete for binding. This is because the peptide within the antigen-binding groove influences the binding of TSST-1 (von Bonin et al. 1995; Wen et al. 1996). TSST-1 binds only to a subset of class II molecules containing the appropriate peptides to which SEB does not bind. Thus, TSST-1 exploits the extreme variability of the MHC-bound peptides for its superantigenic toxins. The crystal structure of SEH (which does not bind to the α chain) complexed with HLA-DR1 also shows an interaction of the superantigen with the peptide (Petersson et al. 2001). The same may be true for other PETs of this group.

Members of groups III, IV, and V use another binding site at the polymorphic β chain of the class II molecule involving the Zn^{2+}-binding site. This binding is of high affinity and uses a bridge between the Zn^{2+} bound to, for example, SEA (via His-187, His-225, and Asp2-27) and His-81 of the MHCII β chain (Abrahmsen et al. 1995; Hudson et al. 1995). Details of this interaction are described in reviews (Svensson et al. 1997; Papageogiou and Acharya 2000).

Members of the SEA group (except SEH) use this mechanism in addition to the α-chain-binding site. Thus, SEA and similar toxins are able to bind with two distinct binding sites to two different sites on the class II molecule and are, as a consequence, able to crosslink class II molecules on the surface of the presenting cell on its own, in the absence of a T cell. It has been shown that this crosslinking leads to transduction of signals in the cell, resulting in cytokine production in monocytes or costimulation of B cells (Mourad et al. 1990; Fuleihan et al. 1991). SEA competes with SEB and TSST-1 for binding.

Some PETs have the ability to form homodimers and in this way form functionally divalent molecules that are also able to crosslink class II molecules (Papageorgiu and Acharya 2000). The streptococcal SPEC forms a noncovalent homodimer which binds only to the β chain of the class II molecule by a Zn^{2+}-mediated binding. The low-affinity α-chain-binding sites of SPEC are covered by the dimerization (Roussel et al. 1997; Li et al. 1997, 1998). SED has been reported to form a zinc-dependent homodimer (Al-Daccak et al. 1998).

NON-MHC RECEPTORS

Under certain conditions SEs have also been shown to activate T cells in the absence of class II molecules on accessory or target cells. Cytotoxic T cells can, for example, lyse target cells that do not express class II molecules; however, much higher concentrations of SEs are required (Dohlsten et al. 1991; Herrmann et al. 1991). This is not surprising given the fact that PETs can interact directly with the TCR (see below), so a superantigen bound to any surface can in principle activate T cells. Whether there is a second specific receptor or whether the SEs nonspecifically stick to the surface of certain cells is unclear. Additional receptors have also been postulated, e.g. on endothelial cells or on thrombocytes, but have not been characterized (reviewed in Fleischer and Hartwig 1992). It is unclear whether such non-MHC receptors play any physiological role.

INTERACTION WITH THE TCR

The major interaction site on the αβ TCR is the variable part of the β chain (Vβ). Stimulation of murine or human T cells with a given toxin in vitro (Table 3), leads to selective expansion of $CD4^+$ and $CD8^+$T cells carrying certain Vβ (Janeway et al. 1989; Kappler et al. 1989; White et al. 1989). A similar preference (for Vγ) was reported for the response of γδ T cells. Transfer of a given Vβ or of an epitope of the hypervariable region 4 of the Vβ, transfers the specific response of the T cell to the recipient T cell (Choi et al. 1990b; Fleischer et al. 1996). The hypervariable region 4 is not involved in peptide-antigen recognition and is located on an exposed lateral region. It is important to note that different Vβs bind to different toxins with different affinities, so T cells with the highest affinity for a given toxin are preferentially expanded in bulk culture. This notion explains that T cells with certain Vβ can respond to a toxin that are not preferentially expanded in such bulk cultures (Fleischer et al. 1991, 1996).

From structural and mutational data a model of the ternary complex of SEB, TCR, and MHCII molecule was hypothesized. The complementarity-determining regions of the TCR are oriented over the MHC peptide-binding site, with the Vβ domain bound to SEB and the Vα domain above the class II β1 domain (Jardetzky et al. 1994). This model is consistent with the findings that the TCR α chain and the polymorphic MHC allotype influence the response of the T cell to some superantigens. In the ternary complex involving SEB the TCR interacts directly with the class II molecule, this is not the case with, for example, SEH (Petersson et al. 2001). Thus individual superantigens vary in the way they crosslink TCR and MHC II.

More recently, a soluble TCR Vβ chain has been used to analyze the binding of PET. The soluble β chain had the same specificity for different PETs as the T cell from which the β chain was derived. Affinities ranged from 0.9 μmol/l to 140 μmol/l, similar to what had been found for the affinities of the TCR to specific peptide/MHC complexes (Li et al. 1998). The three-dimensional structure of the complex between a soluble TCR β chain and

Data are compiled from the literature. Note that determinations have been made in many cases with native and not with recombinant proteins; therefore Vβ specificities of SE and SPE may be affected by contaminations with other toxins, e.g. stimulation of human $V\beta2^+$ and $V\beta8^+$ T cells reported for native SPEA (Abe et al. 1991), and of $V\beta8^+$ T cells reported for native SPEC (Tomai et al. 1992), is not found with recombinant toxins (Braun et al. 1993). Vβ profiles were assayed by polymerase chain reaction or by Vβ-specific antibodies.

SEC3 was determined. The complementarity-determining region (CDR) 2 of the β chain and, to lesser extents, CDR1 and the hypervariable region 4 (HV4) bind in a cleft between the small and large domains of the SE (Fields et al. 1996).

In spite of the requirement for class II molecules in T-cell stimulation, the toxins can also stimulate T cells in the absence of class II molecules. SE-mediated cytotoxicity has been found against several class II-negative target cells (Dohlsten et al. 1991; Herrmann et al. 1991). SEA covalently linked to antibodies against any cell surface molecule can direct lysis of cytotoxic cells to class II-negative target cells (Dohlsten et al. 1991) and toxin bound to plastic can under certain conditions activate T cells (Fleischer et al. 1991). It is noteworthy that some PETs, e.g. SPEC and SPEG and SEH do not stimulate mouse T cells at all, although they do bind to murine MHCII molecules (Proft et al. 1999; Petersson et al. 2001).

The molecular mechanism of T-cell stimulation is thus a multivalent crosslinking of TCR molecules with MHCII molecules on the presenting cell. This crosslinking of the TCR, however, requires – at least at low toxin concentrations – additional adhesion molecules, such as CD2, CD11a, or CD28. The CD4 or CD8 molecules appear not to be required, although in some cases CD4 interaction augments the response (Sekaly et al. 1991). By using this molecular mechanism the superantigen uses the most efficient way to stimulate T lymphocytes. The use of class II molecules as specific receptors restricts the T-cell interaction to the professional APCs, most probably the dendritic cells because macrophages are dispensable to T-cell activation in vivo (Bette et al. 1993).

Biological significance of pyrogenic exotoxins

ROLE OF PYROGENIC EXOTOXINS AS VIRULENCE FACTORS

Although superantigens act on T cells of different species, it appears that they work best in the species that is a natural host for the producing pathogen. The toxins derived from *S. aureus* and *S. pyogenes* (bacteria not found in wild mice) stimulate human T cells much more efficiently than murine T cells, whereas the opposite is true for the mitogen derived from *Mycoplasma arthritidis* (a natural pathogen for rodents) (Fleischer et al. 1991). TSST-1 or SEC produced by ovine strains of *S. aureus* is much more efficient on ovine T cells than on human T cells (Lee et al. 1992; Marr et al. 1993). This suggests that these molecules have been adapted in evolution to the MHC and TCR molecules of the natural host. Acquisition by gene transfer of toxin genes and their subsequent mutation is probably the mechanism of such adaptation, such as transfer of *tst* genes from human to ovine and bovine *S. aureus* strains.

For several reasons it may be expected that the production of a superantigen offers an evolutionary advantage for the respective pathogen. First, the molecular mechanism of action, the crosslinking of TCR Vβ with class II molecules, has evolved several times separately in evolution. Second, the extensive genetic polymorphism of the PETs argues that the presence of multiple forms of a superantigen is advantageous for the producing species. Finally, it appears that superantigens have been adapted by the producing pathogen to the host's immune system, because they have the highest mitogenic potential in the immune system of their respective natural host.

Thus, the evolutionary advantage can be expected to be directly or indirectly linked to the T-cell stimulatory function of superantigens. This has indeed recently been shown for the mouse mammary tumor viruses: T-lymphocyte stimulation is required for effective multiplication and transmission of the virus as discussed below (Held et al. 1994). For the gram-positive cocci there is so far no clear evidence where the advantage of T-cell stimulation lies. The decisive mechanisms against these extracellular bacteria are granulocytes, antibodies, and complement. It is, however, noteworthy that production of a superantigen leads to delayed clearance of *S. aureus* in infected mice (Rott and Fleischer 1994). Moreover, it has been repeatedly shown that humoral and cellular immune responses are diminished if an SE is injected along with a conventional antigen.

ROLE IN PATHOGENICITY

Given the extremely low concentration of picograms per milliliter required for T-cell stimulation and the large amounts of toxin secreted by some strains of staphylococci and streptococci into the culture medium, it is clear that a small focus of bacterial infection can be sufficient to induce a general activation of the immune system and a massive expansion of responding T cells. In patients with toxic shock caused by TSST-1-producing *S. aureus*, $V\beta^+$ cells expand to up to 70 percent of all peripheral blood T cells (Choi et al. 1990a). Consequences of such polyclonal T-cell stimulation can be shock, immunosuppression, and autoimmunity.

The shock-like symptoms induced by these toxins are caused by a massive release of lymphokines (e.g. tumor necrosis factor-α (TNF-α), interferon-γ (IFN-γ), interleukin-2 (IL-2)) and monokines (IL-12). Critical mediators in this shock-like symptom are apparently TNF-α and IFN-γ, both of which are produced by T lymphocytes (Miethke et al. 1992; Bette et al. 1993). The same mediators are involved in the septic shock induced by endotoxin of gram-negative bacteria. It appears that, although distinct cell populations are stimulated in gram-positive and gram-negative shock, a similar cytokine cascade is initiated that ultimately leads to the same terminal events. It is remarkable and still not explained in detail that lipopolysaccharide (LPS) and superantigen potentiate their effects if acting simultaneously in vivo.

Toxic shock syndrome (TSS) is observed during human infections with *S. aureus* and *S. pyogenes*. It is interesting to note that not all SEs have been implicated in such diseases. So far TSST-1 and SEB are almost exclusively involved in staphylococcal toxic shock. Although the gene for TSST-1 is widely distributed among staphylococci, a single *S. aureus* clone accounts for the majority of toxic shock cases in five countries (Musser et al. 1990). This indicates that not the superantigen alone but rather a combination of virulence factors determines pathogenicity. A greater heterogeneity was found with *S. pyogenes* isolates from patients with streptococcal TSS-like syndrome. Here, the ability to cause this syndrome is associated with all of the known SPEs, but SPEA-producing bacteria cause a high proportion of cases. Interestingly, two of four *speA* alleles were present in single bacterial clones that caused the great majority of these cases (Nelson et al. 1991). As a result of the higher invasiveness of *S. pyogenes* streptococcal TSS is associated with higher mortality and certain M types are more strongly associated with TSS than others (reviewed by McCormick et al. 2001).

Immunosuppression can result because stimulation of many T cells will impede the coordinated immune response. Moreover, a toxin can induce anergy and death by apoptosis in those T cells responding to it. After injection of an SE into mice, the initially responding T cells are partially deleted and those remaining in the spleen no longer respond to staphylococcal

enterotoxin B or to anti-TCR antibodies. It is also conceivable that activated $CD8^+$ T cells could destroy APCs or B lymphocytes that have toxin molecules bound to their class II antigens.

ASSOCIATION WITH AUTOIMMUNITY

The polyclonal activation of T cells by PETs could bypass the control of autoreactive T cells or helper T cells could be focused on autoreactive B cells and induce autoantibody production. This may be of relevance, e.g. in streptococcal diseases that are associated with autoimmune phenomena. Stimulation of autoreactive B cells by crossreactive epitopes of, for example, M proteins and the generation of help from T cells stimulated by erythrogenic toxins may provide a pathogenic mechanism. The requirement for such an interaction of two different pathogenicity factors of group A streptococci could explain why such poststreptococcal autoimmune diseases are relatively rarely found. In experimental models it was shown that control of autoreactive T cells could be bypassed by injection of a superantigen (Schiffenbauer et al. 1998). An ongoing autoimmune reaction against brain or joint antigens was aggravated by the injection of a superantigen (Cole and Griffiths 1993; Schiffenbauer et al. 1998). Moreover, a resolved experimental allergic encephalomyelitis could be re-exacerbated by injection of a superantigen stimulating the appropriate autoreactive T cells. Moreover in naïve animals a polyclonal T cell activation by a superantigen could prime Vβ-specific T-cell reponses to a selfantigen by a non-Vβ-specific mechanism of 'innocent' bystander activation (Rott et al. 1995).

Interest has been focused on the findings of an increase in $V\beta2^+$ and $V\beta8^+$ T cells in Kawasaki's syndrome, an acute multisystem vasculitis in children. Staphylococci and streptococci producing PETs have been isolated from these patients, their pathogenic relevance is, however, still unclear (Freeman and Shulman 2001).

In patients with atopic dermatitis, a chronic inflammatory skin disease associated with pruritus and elevated serum IgE, persistent colonization with *S. aureus* is a well-known feature. There is evidence that SEs produced by the staphylococci have the potential to trigger the chronic T-cell-mediated skin inflammation (Herz et al. 1998). It is also a common observation that exacerbations of psoriasis are often associated with streptococcal infections and a causal link has been suggested (Ortonne 1996).

THE ENTEROTOXIC ACTIVITY

The staphylococcal enterotoxins are named for their ability to induce a gastrointestinal illness on oral uptake of a few micrograms within 2–4 h in primates. Studies with mutant molecules (Hufnagle et al. 1991; Harris et al. 1993) and with chemically modified SEs (Alber et al. 1990) indicate that the enteropathogenicity of SEs is not caused by an action on T cells. It has been suggested that the symptoms of the gastrointestinal intoxication are caused by leukotrienes and histamine released from mast cells in response to substance P in the mucosa (Alber et al. 1989). The receptors involved are still obscure.

MYCOPLASMA ARTHRITIDIS SUPERANTIGEN

Mycoplasma arthritidis is a pathogen for rodents and induces an acute inflammatory infection in rats and mice. In mice this inflammation is followed by a chronic joint disease. Cell-free supernatants of *M. arthritidis* contain a potent T-cell mitogen, acting on T cells of several species. Although this mitogenic principle has been known of for more than 15 years (Cole and Atkin 1991), only recently has the protein been cloned (Cole et al. 1996). This is a result of the small amounts of M. arthritidis superantigen (MAS) in the mycoplasma culture and of the lability and adhesive property of MAS. MAS is a hydrophobic and basic peptide that is heat labile at 56°C and susceptible to serine proteases. The sequence reveals a protein unrelated to any other superantigen with 153 amino acids and a calculated molecular mass of 25 kDa and a very basic p*I* of 10 (Cole et al. 1996).

Mycoplasma arthritidis superantigen has all the functional properties of superantigens (Matthes et al. 1988; Cole et al. 1990). Its T-cell stimulatory properties are strictly dependent on the presence of H2-IE molecules or HLA-DR molecules on the stimulating cells. MAS stimulates both $CD4^+$ and $CD8^+$ T lymphocytes and responsive γδ T cells have been described. There is a preferential stimulation of mouse T cells expressing Vβ6, 8.1, 8.2, and 8.3, and of human T lymphocytes expressing Vβ17.1 (also designated 19.1). In addition, there are other TCRs that respond to MAS, but with lower affinity (Fleischer et al. 1991).

Injection of MAS into experimental animals induces a mild toxic shock syndrome and pronounced T-cell suppression (Cole and Wells 1990). This is only found in MAS-responsive mouse strains that possess H2-IE molecules. The chronic joint disease is induced only by infection with *Mycoplasma* itself or by intra-articular injection of MAS. The role of the superantigen in the induction of the arthritic disease is still not clear. It is noteworthy that MAS injection induces a flare-up in mice that have recovered from a collagen-induced arthritis. It has been noted that some parameters of the *M. arthritidis*-induced disease can also be found in rheumatoid arthritis and that antibodies to MAS are present in some patients with this disease. An involvement of MAS-like superantigens in the pathophysiology of rheumatoid arthritis has been suspected (Knudtson et al. 1997).

YERSINIA PSEUDOTUBERCULOSIS MITOGEN

The three pathogenic species of *Yersinia*, *Y. enterocolitica*, *Y. pseudotuberculosis*, and *Y. pestis*, produce many virulence factors required for survival in the body. *Y. enterocolitica* and *Y. pseudotuberculosis* have been reported to produce superantigens. Although the putative superantigen of *Y. enterocolitica* still awaits isolation and confirmation, a superantigen designated Y. pseudotuberculosis mitogen (YPM) has been purified and cloned (Ito et al. 1995; Miyoshi-Akiyama et al. 1995). YPM is synthesized as a precursor of 151 amino acids which is cleaved to a mature protein of 14 kDa and 131 amino acids. It has no homology with any other superantigen. The protein has all the characteristics of a superantigen in vitro and in vivo. It is produced by certain serotypes of *Y. pseudotuberculosis* with distinct geographical distribution. The gene encoding YPM was detected in 95 percent of clinical isolates of *Y. pseudotuberculosis* from Japan or the far eastern Russian states but only in 17 percent of European clinical isolates (Yoshino et al. 1995). Recently, a variant YPM was isolated and cloned (Ramamurthy et al. 1997). The two YPMs (designated YPMa and YPMb) have 83 percent homology. A third variant was recently described. This indicates that YPM forms a polymorphic family as the SE.

The infection with *Y. pseudotuberculosis* is characterized by acute mesenteric inflammation and lymphadenopathy and systemic symptoms such as fever and leukocytosis. In patients with *Y. pseudotuberculosis* infections an elevation of Vβ3-bearing T cells has been found (Abe et al. 1997). Several immunopathological diseases can follow an infection with *Y. pseudotuberculosis* such as reactive arthritis or uveitis and erythema nodosum. Moreover, Kawasaki's syndrome has been linked to *Y. pseudotuberculosis* infections. A role of the superantigen YPM in the pathology of this infection is conceivable but still not clear. It has been shown in mice that YPM-deficient *Y. pseudotuberculosis* bacteria have a reduced virulence (Carnoy et al. 2000).

MOUSE MAMMARY TUMOR VIRUSES

The first viral superantigens (vSag) described were those encoded by mouse mammary tumor viruses (MMTV), retroviruses that cause mammary carcinomas in mice. In fact these powerful stimulators were known since 1973 as minor lymphocyte-stimulating antigens (Mls) but remained enigmatic (Janeway 1991) until their association with MMTV was found (reviewed in Acha-Orbea and MacDonald 1995).

The superantigen is encoded in an open reading frame encoding approximately 320 amino acids located adjacent to the 3′ long terminal repeat. As with the bacterial superantigens there is extensive polymorphism. All MMTV superantigens show a high degree of sequence conservation with the exception of the carboxy-terminus which shows extensive polymorphism. This part encodes the putative Vβ-binding part of the molecule. The viral superantigen is synthesized as a glycosylated type II membrane protein with an extracellular carboxy terminus and is then proteolytically processed. In CHO cells the superantigen is cleaved by the endoprotease furin and a carboxy-terminal 18-kDa fragment has been shown to be expressed on the surface. Endoproteases are also possibly able to cleave the superantigen (Denis et al. 2000).

It has been noted that the vSags have functional and structural similarities with the MHCII-associated invariant chain Ii. Both are class II membrane proteins of similar size and both associate with class II molecules inside the cell. Both possess a strong and invariant class II-binding motif, the invariant chain Ii has the CLIP sequence, and the vSag has a class II-binding motif at a location corresponding to CLIP in the Ii (Hsu et al. 2001). This motif is conserved in all MMTV superantigens. A model for the association of vSag with class II molecules implies that vSag competes with Ii for binding to the peptide groove of class II αβ dimers in the endoplasmic reticulum. In the trans-Golgi network the vSag is cleaved by furin, yielding the 18-kDa carboxy-terminal fragment of the superantigen that is bound outside the peptide-binding groove (Hsu et al. 2001). After transport to the cell surface the vSag–class II complex is accessible for T cells. The fate of the remaining portion of the vSag is still unclear.

When taken up by the newborn mouse with the maternal milk, the virus infects naïve B cells and immature dendritic cells (DC) (Vacheron et al. 2002) which express the viral superantigen. Infected B cells stimulate T cells carrying the appropriate Vβs which in turn stimulate infected B cells to proliferate and increase exponentially in number (Held et al. 1993). This allows the virus to persist until the mammary gland has matured. Infected mammary epithelial cells produce virus, allowing the transfer to the newborn mouse. Proviral insertion in epithelial cells can lead to activation of endogenous cellular oncogenes and cell transformation.

Mice harboring integrated endogenous MMTVs or a transgenic superantigen delete T cells carrying the Vβ that has reacted with the vSag of the endogenous MMTV. These mice are protected against infectious MMTV with specificity for the same Vβ (Golovkina et al. 1992). MMTVs in which the vSag has been deleted are still fully infectious but are not able to reach the mammary gland to effect transmission.

HUMAN ENDOGENOUS RETROVIRUSES

After the description of the MMTV superantigen many groups searched for viral superantigens in humans. There were a number of reports that described imbal-

ances in Vβ expression in certain human diseases. However, although they were published in first-class journals they remained either unclear or unconfirmed. Rabies virus (Lafon et al. 1992), HIV (Imberti et al. 1991), cytomegalovirus (CMV) (Dobrescu et al. 1995), or Epstein–Barr virus (EBV) (Sutkowski et al. 1996), for example, were proposed to encode superantigens. However, it was not possible to identify clearly the respective gene in these viruses, e.g. by recombinant expression.

Several groups have also provided indirect evidence for the involvement of superantigens in human diseases. In all these cases an imbalance in the Vβ-composition of T cells from patients has been found, e.g. two groups have demonstrated a selective increase in T cells carrying Vβ14 in the synovial fluid of patients with rheumatoid arthritis (Kotzin et al. 1993). Furthermore, an imbalance in the Vβ repertoire of T cells has repeatedly been reported in patients with AIDS, although not confirmed by all investigators. It is still unclear, however, if this is the result of a superantigen produced by HIV or of secondary infection or a nonsuperantigen-dependent mechanism. Although the idea that superantigens are at work in such diseases is very exciting, one has to bear in mind that preferential stimulation of certain Vβ-bearing T cells can also occur during a normal immune response (Boitel et al. 1992).

More recently, however, compelling evidence has been presented by Conrad et al. (1994) that a human endogenous retrovirus encodes a superantigen. The N-terminal moiety of the envelope gene of a polymorphic and defective provirus originally named IDDMK1,2 encodes an MHCII-dependent Sag. This virus, now designated HERV-K18.1, is one of three alleles of the HERV-K18 family of proviruses, each of which encodes a superantigen with specificity for Vβ7 and Vβ13 T cells.

Conrad et al. (1994) had previously observed that $V\beta7^+$ T cells were selectively expanded among islet-infiltrating T cells in two individuals in the early phase of type 1 diabetes mellitus. Moreover there was evidence of positive selection, after exposure to diabetic islet cell membrane preparations, of $V\beta7^+$ T cells from peripheral blood lymphocytes of individuals who did not have diabetes. They proposed that expression of the superantigen from the HERV-K18.1, induced in professional APCs, leads to β-cell destruction via the systemic activation of autoreactive T cells (Conrad et al. 1997).

Surprisingly, however, several other groups have not been able to find evidence for a superantigen in HERV. Lapatschek et al. (2000) amplified by polymerase chain reaction (PCR) and cloned into open reading frames of eukaryotic expression vectors, which were identical or very similar to IDDMK1,2. Although they were able to demonstrate mRNA expression and protein production in A20 B-lymphoma cells they could not find any evidence that the open reading frame (orf)-stimulated human or murine T cells in a Vβ-specific fashion.

An intriguing observation was that expression of HERV-K18 Sags was inducible by IFN-α and this is sufficient to stimulate Vβ7 T cells to levels comparable to transfectants constitutively expressing HERV-K18 Sags (Stauffer et al. 2001). This link between viral infections and IFN-α-regulated Sag expression could be a mechanism through which environmental factors may cause disease in genetically susceptible individuals. This observation was extended to show that EBV transcriptionally activated the viral superantigen, suggesting that the previously described EBV-associated superantigen activity was caused by the EBV-induced activation of the endogenous retrovirus (Sutkowski et al. 2001).

It has therefore been proposed that the superantigen activity found with several human viruses may not be caused by a viral gene product but by the activation, e.g. via IFN, of endogenous retroviral superantigen expression (Woodland 2002). This could explain the failure to identify molecularly such superantigens in rabies virus, CMV, and EBV. It could also explain the Vβ imbalances found in a number of human autoimmune diseases or HIV infection.

MORE SUPERANTIGENS?

In addition to the members of the PET family, there are other staphylococcal and streptococcal proteins genetically unrelated to the enterotoxins that have been proposed as superantigens, such as the streptococcal M protein, the streptococcal erythrogenic toxin B, and the staphylococcal exfoliative (epidermolytic) toxins. However, the evidence discussed below suggests that these molecules are not superantigens but that their mitogenicity is the result of artifacts (Fleischer et al. 1995).

The staphylococcal exfoliative toxins

The exfoliative toxins A and B of *S. aureus* (ETA and ETB) share a high-sequence homology but are serologically unrelated. They are able to dissociate intercellular adhesion molecules in the skin leading to subgranular epidermolysis. Epidermolytic toxin A is synthesized as a precursor molecule of 31 kDa which is subsequently cleaved to the mature polypeptide of 27 kDa. Both ETA and ETB have an intrinsic esterase activity and are homologous to the staphylococcus V8 protease (Bailey and Redpath 1992). They share the catalytic triad at the protease active center. Mutation of the serine of the active center leads to loss of epidermolytic activity in mice. ETA was reported to be a superantigen stimulating $V\beta2^+$ T cells (Marrack and Kappler 1990).

However, it was subsequently shown that ETA does not bind MHCII molecules (Herrmann et al. 1989) and that recombinant ETA produced in S. aureus had no

mitogenic activity toward human peripheral blood mononuclear cells (PBMC) or Vβ2$^+$ T cells (Fleischer and Bailey 1991). More recently, it was described that both ETA and ETB in recombinant form stimulated human Vβ3, -12, -14, -15, and -17 T cells, a profile that is very similar to that of SEB and SEC. MHCII binding was not investigated. In in vivo tests for pyrogenicity only ETB, but not ETB, showed pyrogenic activity (Monday et al. 1999), one of the hallmarks of superantigens. The question if the exfoliative toxins are superantigens (or T-cell-specific mitogens at all) is thus not unequivocally settled.

M proteins and SPEB of *S. pyogenes*

M proteins of *S. pyogenes* are major virulence factors of group A streptococci. They are receptor proteins that show multiple binding to different plasma proteins and protect streptococci against phagocytosis. They form a family of closely related proteins protruding from the cell surface. The variable M-terminal portion of the molecule carries the M-type-specific antigen epitopes. M-protein fragments produced by limited proteolytic digestion of whole streptococci with a molecular mass of 33 kDa (pepM5) have been proposed to be superantigens and to stimulate Vβ2$^+$, 4$^+$, and -8$^+$ human T cells (Tomai et al. 1991, 1992).

If, however, M5 protein or pepM5 is thoroughly purified, it is no longer mitogenic (Fleischer et al. 1992; Degnan et al. 1997). The stimulatory activity for Vβ2$^+$ and Vβ8$^+$ T cells could be separated from each other, suggesting that the superantigenic activity of M protein type 5 could be caused by contamination with at least two different, possibly novel, streptococcal PETs (Schmidt et al. 1995). Recombinant M5 protein or its fragments were not mitogenic (Robinson et al. 1991; Schmidt et al. 1995; Degnan et al. 1997).

Taken together, the available evidence strongly suggests that mitogenicity of M-protein preparations is not the result of an intrinsic activity but of contaminating SPEs, some of them not known at the time of the reports. The Vβ pattern matches well the pattern of SPEC, SPEG, and SMEZ.

The same situation was found with the streptococcal erythrogenic toxin B (SPEB) which is identical to the precursor of the streptococcal protease. It is a molecule of 371 residues with 40 kDa of molecular mass and is successively processed to the mature protease of 253 amino acids and 27 kDa. All group A streptococci have SPEB, and there is only one nonpolymorphic gene for this molecule present in the genome. SPEB has no homologies to any member of the staphylococcal enterotoxin family (Betley et al. 1992). SPEB has been reported to stimulate selectively Vβ8$^+$ human T cells. On proper purification of SPEB, however, it became evident that the superantigenic properties of these molecules are caused by contamination with a novel Vβ8-stimulating PET designated SPEX (Braun et al. 1993) and recombinant SPEB was not mitogenic (Gerlach et al. 1994). The Vβ8-stimulator SPEX is identical to a variant of SMEZ (Kamezawa et al. 1997) and has subsequently been cloned (Gerlach et al. 2000).

The mitogenic factor of *S. pyogenes*

A protein of 26 kDa, the so-called mitogenic factor (MF), or SPEF (Norrby-Teglund et al. 1994), was purified from *S. pyogenes* strain NY5 (the prototype strain from which SPEA, SPEB, SPEC, and SMEZ were originally purified). MF is not polymorphic and is elaborated by all group A streptococci, but not by other streptococci. Interestingly, it has enzymatic activity: it is a nuclease (Iwasaki et al. 1997) and is identical with DNase B. The Vβ profile of the stimulated human T cells was recently described to be Vβ2, -4, -8, -15, and -19, and is surprisingly similar to that of pepM5 (Norrby-Teglund et al. 1994). We have not been able to detect mitogenicity with recombinant MF and have recently shown that SPEC and SMEZ are the contaminants causing mitogenicity of MF (Gerlach et al. 2001).

Taken together, these results raise an important caveat for the work with T-cell mitogens from *S. aureus* and *S. pyogenes*. As SE and SPE are active in concentrations of a few picograms per milliliter, the sensitivity of T cells to these stimulators is several orders of magnitude higher than the sensitivity of any biochemical or serological test and contamination with an SE or SPE is extremely difficult to exclude. Such a contamination can even occur if a recombinant protein is purified on columns previously used for purification of natural enterotoxin. Moreover, given the high polymorphism and unequal distribution of the PET it is surprising that nonpolymorphic proteins, such as SPEB or MF, present in all *S. pyogenes* isolates are superantigens. A number of different proteins of *S. pyogenes* have been purified from culture supernatants and have been found to behave like superantigens (Fleischer et al. 1995). The possibility that *S. pyogenes* has evolved several unrelated superantigens is exciting but we should await the confirmation of their activity using recombinant proteins.

The surprising finding that the unique molecular mechanism of T-cell stimulation has been developed completely independently by infectious agents of four very different classes, gram-positive cocci, gram-negative bacteria, *Mycoplasma*, and retroviruses, has led to the expectation that additional superantigens produced by other infectious pathogens would be found. This expectation together with the appealing designation 'superantigens' has induced a boom in reports of putative novel superantigens, usually in high-impact journals. However, the number of reported candidates exceeds by far the number of superantigens that are likely to exist.

Even a lectin has been reported to act as a superantigen (Saul et al. 2000) but this has not been confirmed by an independent group. For several candidates it is already now reported that attempts to confirm the initial claim have failed or have prompted contradiction. We have, for example, not been able to find any superantigenic activity with purified enterotoxin of *Clostridium perfringens*, both purified from *Clostridium perfringens* cultures and as a recombinant molecule from *Escherichia coli* (Krakauer et al. 1997), and also not with exotoxin A of *Pseudomonas aeruginosa* (unpublished observations). Likewise the initial report on a superantigen in *Toxoplasma gondii* was never confirmed (Denkers et al. 1994), and also one in *M. tuberculosis* (Ohmen et al. 1994).

CONCLUSION

The superantigens described in this chapter constitute the most efficient T-lymphocyte stimulators known. Although their exact benefit as virulence factors for the production of bacteria is not established, it is obvious that their induction of immunosuppression, destruction of APCs, and T-cell anergy should be of advantage to the infecting microorganisms. The manifold mechanisms of interaction with variable target structures of the immune system, the MHCII molecule and the TCR, allow a maximum of biological efficacy combined with a minimum of immunological crossreactivity. This is the basis for the extensive polymorphism of the superantigens that provides the producing species with a multitude of non-crossreacting toxins. The polymorphism is probably maintained and extended by permanent modifications of the superantigen genes through mutations and selection for variants that are optimally stimulatory for the host's immune system.

The determination of the complete genome sequence of *S. aureus* has revealed a cluster of genes called the *sets* (Staphylococcal enterotoxin-like toxins) that are resident in a pathogenicity island SaPIn2 and share structural homology to the SEs and SPEs and in particular to TSST-1 (Williams et al. 2000). They form a highly polymorphic family with more than a dozen members and several members are found within a given *S. aureus* strain. The encoded proteins that are secreted have the three-dimensional structure characteristic of the SEs but do not have the classical functions of superantigens, such as mitogenicity, pyrogenicity or the enhancement of endotoxic shock (Arcus et al. 2002).

Recently, Fraser and coworkers have been able to discover a biological function for an SET. SET1 was found to bind to IgA and to inhibit polyclonal IgA binding to Fc-receptors for IgA on myeloid cells. Moreover, SET1 also binds complement C5 with nanomolar affinity and inhibits complement-mediated lysis (Langley et al. in press). This is an exciting discovery showing that superantigen-related molecules that apparently have evolved from a common ancestor target components of the innate immune system and contribute to virulence and pathogenicity.

Knowledge of the human genes involved in determining infectious disease susceptibility will enhance our understanding of the mechanisms of protective immunity and facilitate development of new treatment strategies and prophylactic measures. In some cases, targeting individuals at high risk of chronic manifestations of disease may, where resources are limited, provide a way forward. It is becoming increasingly simp9le to use the multiple polymorphisms available in immune response genes; hence risk prediction will become a realistic possibility in the near future. However, a plethora of small studies appearing in the literature, some of which have little power to reveal minor genetic effects, at present gives an incomplete picture. This chapter concentrates on human rather than murine studies, and common rather than rare genetic variants. It is necessarily a personal view, and does not attempt to list every known gene of interest or every disease investigated. At the start it seems appropriate to highlight the rapid developments not only in human genetics, but also in pathogen sequencing. In the future it will be fruitless to study human or pathogen variation in splendid isolation. Variation in the pathogen may affect virulence and the host immune response. Clearly human and pathogen genetic variations are inextricably linked in determining disease outcome, and their relative importance will vary with disease.

SIMPLE VERSUS COMPLEX INHERITANCE

There are rare single gene disorders that have contributed to understanding of the role of immune response genes and immunological function in infection. Investigations of single gene disorders show that individual mutations may not be the sole determinants of phenotype. Other influences can modify the phenotype, and disease may have a threshold for manifestation. Hence, some disorders that have been regarded as simple Mendelian disorders are now better described as 'complex' traits. A range of mutations, such as seen in the tumor necrosis factor (TNF) receptor gene *TNFRSF1A*, means that some mutations result in immune dysfunction, and others may be low penetrance (i.e. not always expressed) rather than benign mutations (Aksentijevich et al. 2001). Similarly, development of an infectious disease, or position on the disease spectrum, is likely to be caused by an accumulation of predisposing factors, including susceptibility alleles. Most variation in disease susceptibility will be 'multifactorial' i.e. with both genetic and environmental influences. Genetic variation is likely to be polygenic, with many contributing genes and disease resulting from multiple common variants in polymorphic genes, rather than from rare mutations. Examples of genes that were

initially shown to have rare deleterious mutations, and are now studied for common nonpathogenic variants, are the interferon receptor genes *IFNGR1* and *IFNGR2* (Gao et al. 1999). It is likely that most variation underlying disease is caused by mildly deleterious alleles. The frequency of susceptibility alleles may be high, and there is likely to be allelic heterogeneity between populations (Pritchard 2001). For immunogenetic studies, assumptions are often made of low allelic heterogeneity within loci, which, when combined with a lack of knowledge of linkage disequilibrium, makes the interpretation of results challenging.

DEFINING CLINICAL PHENOTYPE

One of the key issues for genetic studies is that of defining the clinical phenotype. Most investigations are conducted using qualitative traits, e.g. disease versus absence of disease. However, quantitative traits are also employed, particularly for immune responsiveness in relation to disease. Nongenetic effects, such as routes of infection, age, and sex, must also be accounted for. Although genetic studies have the advantage that DNA may be sampled at any time, and do not require active disease, it is clear that samples pertaining to chronic disease states are more often collected, whether for family or case–control studies. A major problem for an infectious disease is ensuring that disease-free individuals are really resistant, rather than simply not exposed to the infection. For many infections exposure is hard to quantify, although for mycobacterial infections a positive skin test response to crude mycobacterial antigen can be used as an indicator of exposure. Some of the most effective studies do not concern susceptibility to disease itself, but to type of disease, which is often related to the ability to mount an appropriate immune response. Consequently, diseases that have a spectrum of severity, such as mycobacterial and protozoal diseases, have been relatively well studied.

TESTING FOR GENETIC CONTROL

Familial clustering of disease, twin studies, and racial differences may all point to genetic control. Adoptee studies are rare and not appropriate for infectious diseases. A statistic commonly associated with multifactorial conditions is λ_s, the risk to a sibling of an affected case compared with the population prevalence – the higher the value, the larger the role of genetics. However, shared sibling environment makes such estimates unreliable and they are not in common usage for infectious diseases. Nutritional status and co-infections may also be confounding factors. Another statistic is heritability: the proportion of phenotypic variation resulting from genetic causes. It is often used for quantitative traits such as pathogen burden or immune responses. The heritability of immune responses to many pathogen antigens tends to be high, with some of this being the result of non-major histocompatiblity complex (MHC) control.

Segregation analyses are formal tests of the fit of family data to models of inheritance. The occurrence of disease at random in the population is tested using a sporadic model. Rejection of a sporadic model shows a nonrandom distribution of disease. Further models can then be tested, comparing specific modes of inheritance (e.g. single gene control) with polygenic and nongenetic models. Although many segregation analyses for infectious diseases have favored single major gene control, this may reflect the choice of models that have been tested and the limitations of analytical methods.

APPROACHES FOR GENE IDENTIFICATION

Having established that there is genetic control, there are two approaches to gene identification: candidate gene testing and genome scanning. Candidate genes may be genes relevant to the immune response, associated with other similar diseases, implicated in murine model systems or within regions highlighted by genome scans. Genome scanning, as the name implies, covers the entire genome equally in the search for regions controlling susceptibility. Ideally we would like to ascertain not only the number of genes contributing to infectious disease susceptibility but also how they interact – additively or multiplicatively? The relative risk of disease for a particular gene will contribute to the ability to detect its effect. In general methods may loosely be categorized as based on linkage or association, the latter relying on linkage disequilibrium (Ott and Hoh 2000). Whereas linkage is employed for genome scanning, association is often the method of choice for a candidate gene approach. Investigators of other multifactorial conditions, particularly those studying autoimmunity and type 1 diabetes mellitus, pioneered methods of analysis.

LINKAGE

Linkage studies are used to identify broad regions of the genome involved in disease susceptibility. Historically, linkage formed part of a positional cloning strategy. However, with the sequencing of the human genome the necessity for positional cloning has been reduced. Laboratory mice, which can be maintained in environmentally controlled conditions, have been important in linkage mapping and locus identification, because there is much conserved synteny between murine and human genomes (groups of genes in which the order is conserved). Use has been made of recombinant inbred, congenic, and more recently recombinant congenic strains (Fortin et al. 2001b). Recombinant congenic strains are derived from backcrossing of a background strain and a donor strain, followed by brother–sister

mating where each resulting strain carries about 10 percent of one parental strain on the genetic background of the other. These strains are used when a limited number of genes have a major effect on phenotype (Malo and Skamene 1994). Transgenic and knock-out mice have been used to confirm findings. Some of the genes identified in mouse models have been catalogued (McLeod et al. 1995), but only selected examples are mentioned in this chapter.

Microsatellite markers, particularly dinucleotide repeats, are usually the polymorphisms of choice for linkage studies. This is because they are highly polymorphic, as measured by polymorphism information content (PIC) or heterozygosity; hence they maximize the information from a given dataset. Haplotypes, using more than a single polymorphic site, can also be used to improve information content. Repeatability of linkage results within a population is essential, and genome scans often adopt a staged approach, with initial results tested in other independent samples. Most genetic markers are expected to be in Hardy–Weinberg equilibrium, and deviations could be indicative of selection or genotyping errors.

There are two methods of linkage analysis: model dependent, where a mode of inheritance must be specified, and model free. The LOD score method is used for parametric, model-dependent analysis and is powerful. A LOD score is the logarithm of odds ratio, where the ratio is the likelihood of the observed results given linkage to a given locus at a recombination fraction of <0.5, over the likelihood under a null hypothesis of no linkage. A maximum likelihood ratio can be expressed as a probability or p value (Nyholt 2000). A LOD of 3 has been used as significant evidence of linkage for mendelian traits, and a LOD of -2 as indicative of no linkage. Multipoint analysis, which combines information from multiple loci to localize a disease susceptibility locus on a genetic map, can result in increased power, but such methods are affected by pedigree size and incomplete pedigrees. Use of single large pedigrees, with or without inbreeding, is uncommon for infectious disease (Farrall 1993). Parametric analysis is thought to be sensitive to model misspecification; however, Greenberg et al. (1998) suggested that the critical factor in LOD score analysis is the mode of inheritance for the linked locus, not that of the disease or trait itself. It is easy to examine parent-of-origin effects using parametric methods. This has been employed in studies of asthma and atopy. True combined segregation and linkage analysis, where the mode of inheritance of a disease is assessed at the same time as linkage status of a disease susceptibility locus, is also a parametric method. It is more common for studies to employ a previously ascertained mode of inheritance when assessing linkage. This is simpler but more limited.

Nonparametric methods are not model dependent and often use affected sibling pairs rather than large pedigrees. This use of only affected individuals neatly gets round problems of exposure for infectious disease. Such methods examine alleles or haplotypes from the parents shared by affected sibs (identical by descent (IBD)). Correction may be made for multiple sib-pair comparisons within a family. A contrasting method examines alleles shared by affected relative pairs (identical by state (IBS)). IBS methods have been regarded as less powerful than IBD methods, because they may lose information, although the choice depends on the family structure available. For high relative risk and PIC values distant relatives are better for affected pair methods, whereas for smaller relative risks and PIC values sibs are best (Risch 1990). Attempting to circumvent some of the problems are programs such as GENEHUNTER, which uses all pedigree members in a multipoint approach (Kruglyak et al. 1996). Kruglyak et al. (1996) argue that their nonparametric linkage (NPL) method shows little loss of power compared with parametric methods and is less sensitive to misspecification of allele frequencies, for pedigrees of moderate size.

There are a number of linkage methods appropriate to the study of quantitative traits based on robust regression and powerful variance component methodologies (Sham et al. 2002). In some instances extreme discordant or concordant sibs are selected. Variance component methods are often used, looking at allele-sharing probabilities and the contribution to population variance. Variance may be partitioned into that caused by environmental effects, a major gene, plus other genes, and methods are implemented by programs such as GENEHUNTER (Pratt et al. 2000).

When genome scanning, approximately 300 microsatellite markers are tested for linkage. The amount of correction of the statistical significance of genome scanning results needed to allow for multiple comparisons is controversial; methods are reviewed, and accepted thresholds for genome-wide significance and corrections for multiple testing discussed (Nyholt 2000). Overly cautious approaches will cause loose linkages to be missed; however, enthusiastic reporting will cause confusion. Point-wise and genome-wide significance levels differ (Lander and Kruglyak 1995). Some believe that the degree of type 1 error for claims of linkage and association in complex inheritance is unacceptably high (Morton 1998).

An interesting question arises over the power needed to detect necessary versus susceptibility loci (Greenberg 1993). Whereas linkage is ideal for looking for loci that are necessary if not sufficient, it may be less than ideal for loci that are neither necessary nor sufficient, i.e. susceptibility loci. If the allele confers less than 10 times an increase in risk, as is the case for almost all infectious disease loci, linkage is hard to use. The numbers used for affected sib-pair genome scanning are often in the region of 200 sib-pairs plus parents (800 individuals). Population size and levels of inbreeding affect numbers

required for all types of linkage and association studies. In large populations heterogeneity is often addressed by studying large numbers of families; however, in founder populations there is presumed to be decreased heterogeneity and fewer susceptibility alleles (Ober and Cox 1998).

ASSOCIATION

Association methods are often used after linkage studies for fine mapping, or for candidate gene approaches. They rely on linkage disequilibrium – the nonrandom assortment of alleles at adjacent loci within the population. The closer together two loci are, the less likely it is that a particular haplotypic combination will be separated by recombination. Such combinations may also result from admixture, selection, or drift. One cannot assume that the polymorphism under investigation is itself functionally relevant, but rather that it is used as a marker for a small region. As association methods rely on the presence of linkage disequilibrium, they are applicable only over short genetic distances. Many association studies use a case–control design. Typically a chi-squared test is employed, and Fisher's exact test may be required, depending on allele frequencies. It is possible to look at association with alleles (if the Hardy–Weinberg equilibrium holds), genotypes, or carriage (presence versus absence) of a particular allele. Whereas genotypic association is most appropriate for many loci (Sasieni 1997), carriage is appropriate for studies of human leukocyte antigen (HLA). Stratification of data, e.g. by HLA type, to look for more minor genetic influences is often used. Approaches for association mapping, analogous to multipoint linkage mapping, still need to be developed. The degree of linkage disequilibrium will determine the density of markers required to examine a region. Linkage disequilibrium is not uniform over the genome, with estimates ranging from 500 to <50 kb (Abecasis et al. 2001). In addition, linkage disequilibrium appears to be highly structured into discrete blocks, separated by hot spots of recombination (Goldstein 2001). Population size and population history will also affect the degree of linkage disequilibrium. In isolated populations there are limited ancestral haplotypes, and if a mutation is new there will be high linkage disequilibrium. However, results to date suggest that genetic isolates (unlike for linkage) will not prove more useful than larger populations for linkage disequilibrium mapping (Eaves et al. 2000), i.e. levels of linkage disequilibrium are equivalent across populations of varying sizes.

Case–control studies are potentially affected by population stratification; this occurs where the frequencies of both the disease and unlinked alleles vary between populations, and can lead to false-positive or false-negative results. The extent of problems caused by population structure has been questioned, but, to avoid such problems, the transmission disequilibrium test (TDT) is increasingly used to test for association. It is a family-based method, which observes transmission of alleles from heterozygous parents preferably to a single affected child, and is typically implemented in a variety of programs such as ETDT (Sham and Curtis 1995). Transmissions may be from the paternal or maternal side. Although originally described by Spielman et al. (1993) as a test of linkage in the presence of association, the tightness of linkage inferred by this method is debatable (Whittaker et al. 2000); however, as a test of association it avoids problems of population subdivision and admixture (Ewens and Spielman 1995). If parents of affected offspring are not available, deduction of missing parental genotypes can introduce bias, and use of unaffected siblings as controls has been suggested (Curtis 1997; Spielman and Ewens 1998). The haplotype relative risk (HRR) method also gets round population stratification, by using the set of alleles that were not transmitted as controls (Knapp et al. 1993). The TDT, together with the HRR, is the most widely used family-based test for linkage disequilibrium and association (Spielman and Ewens 1996). However, this approach may be less powerful than that of a case–control. TDT can also be performed for quantitative traits (Allison 1997; Rabinowitz 1997; Abecasis et al. 2000).

Association methods are more powerful than linkage, as confirmed by stimulation studies comparing TDT and affected sib-pair methods (Risch and Merikangas 1996). Knapp (1999) gives further consideration to power approximations for the TDT. Sample sizes for TDT have been calculated (Wang and Sun 2000). As for linkage analysis, the need for correction of multiple comparisons when interpreting case–control and family-based association studies has been much discussed. The Bonferroni correction method is most widely used (Bland and Altman 1995) and also the Holm method (Aickin and Gensler 1996). Exactly when to correct has been debated and correction is certainly not uniformly applied (Nyholt 2001). There are now many disease associations in the literature, in many populations. Heterogeneity of findings, even to the extent of positive versus no association in the same population group, is commonplace, and probably reflects both publication bias and the small size of many studies. Recent guidelines for the interpretation of association studies suggest that results should be confirmed with a second study, with $p < 0.001$, similar to the two-stage genome scans for linkage. Meta-analyses are likely to be needed to confirm associations: recent meta-analyses of genetic association studies suggest that only 20–30 percent of association studies are significant and 16 percent of reported associations are supported by further studies (Ioannidis et al. 2001, 2003; Lohmueller et al. 2003). Although not considering specifically infectious disease associations, such studies suggest that many of the reported associations will prove to be false.

The future will bring genome scanning by association using single nucleotide polymorphisms (SNP). It is estimated that there is more than 1 SNP per 1000 base-pairs, or more than 3 million in the genome. They may occur in coding sequences and are more stable than microsatellites. Large-scale identification and screening for SNPs is now possible (Wang et al. 1998, see www.ncbi.nlm.nih.gov/SNP/). How polymorphic and densely spaced should SNPs be for a genome scan? One suggestion is that 7–900 moderately polymorphic SNPs, and a map of 1 500–3 000 SNPs, would be superior to the current microsatellite linkage strategy (Kruglyak 1997). Alternatively, a level of linkage disequilibrium of 3 kb would suggest that half a million SNPs are required (Kruglyak 1999)! Use of haplotypes may reduce the number of SNPs required for screening of complex disease (Johnson et al. 2001), as demonstrated by looking at the haplotypic structure of 5q31 (Daly et al. 2001). However, the nonuniformity of linkage disequilibrium in different regions of the genome (Collins et al. 1999) suggests that SNPs for whole genome scanning will have to be suitably chosen region by region.

SINGLE GENE CONTROL OF THE IMMUNE RESPONSE AND BEYOND

It is beyond the scope of this chapter to catalogue primary immunodeficiencies that have been well reviewed elsewhere (Fischer et al. 1997). In general these are rare disorders, in some cases recognized as single gene disorders through pedigree analysis. Many are lethal and some disorders are associated with multiple rare mutations. In other single gene disorders, the gene may be localized but not identified. However, it is worth noting that, according to the defect, infection is likely to be with characteristic pathogens. Some of these opportunistic infections are not usually associated with pathogenicity. Defects of the adaptive immune response include defects in MHC, particularly defects in expression such as bare lymphocyte syndrome (BLS), defects in T-cell development and function, such as the severe combined immunodeficiencies, e.g. X-SCID, and defects in B-cell function with numerous irregularities in immunoglobulin production. Defects also occur in the innate immune response such as those of phagocytic cells, e.g. chronic granulomatous diseases. Somewhat more common are deficiencies in the classic and alternative complement pathways. Whereas defects in classic components tend to result in the autoimmune disorder systemic lupus erythematosus, defects in the membrane attack complex predispose to pyogenic bacteria (Walport 1993). Single gene disorders affecting nonimmune response genes are also associated with particular pathogens. Individuals homozygous for mutations in *CFTR*, resulting in cystic fibrosis, are susceptible to *Pseudomonas aeruginosa*.

Interest in MHC class II expression was the result of expression being inducible by stimuli such as interferon γ (IFN-γ). Cells in BLS have no MHC II molecules. The story of BLS is pleasing for geneticists because heterogeneity in BLS was characterized by classic genetic complementation analysis in culture. There is a defect at the level of transcription, associated with the highly conserved X and Y boxes in the promoters of all class II genes. Complementation group A is caused by the absence of the *trans*-acting factor CIITA (MHC class II transactivator), which is a non-DNA-binding co-activator, necessary for activity of the class II promoter. Complementation groups B and C, on the other hand, are the result of deficiencies in the X-box-binding protein RFX, which is composed of a 75-kDa and a 36-kDa subunit. Failure of RFX to bind to the X box leaves the class II promoter unoccupied, and is associated with change in chromatin structure and the loss of DNase I hypersensitive sites (Reith et al. 1995; DeSandro et al. 1999).

X-linked SCID is the most common form of severe combined immunodeficiency. T and natural killer (NK) cells are affected whereas B-cell function is largely intact. The interleukin-2 (IL-2) receptor is made up of three chains: α, β, and γ (now named 'common γ' or γc). The γc chain is responsible for increasing the binding affinity of the receptor and is involved in intracellular signal transduction; it is also an essential component of other cytokine receptors: IL-4R, IL-7R, IL-9R, and IL-15R. Mutations in the gene for γc result in X-SCID (Sugamura et al. 1996; Cacalano and Johnston 1999). It appears that the primary mechanism of X-SCID is through the absence of the IL-7R necessary for T-cell development (Puel et al. 1998). Mutations in the α chains of both the IL-2R (Sharfe et al. 1997) and the IL-7R (Roifman et al. 2000) also occur. Cytokine receptors are often heterodimers or heterotrimers, and the phenomenon of chain sharing is not uncommon (e.g. the IL-4R chain occurs in both the IL-4 and the IL-13 receptors). This means that their binding specificities may have some overlap, but also that mutation in one chain may have far-reaching consequences. Mutations in signaling molecules, e.g. the Janus kinases, associated with these receptors are responsible for similar phenotypes. A few single gene defects, such as that identified in *IFNGR1*, are described together with the effect of more common variants of the same gene.

Defects in immunoglobulin (Ig) production are characterized by too much or too little of a particular Ig class or subclass. Some of these are caused by failure in class switching. Hyper-IgE syndrome presents as an autosomal dominant disorder with variable expressivity and is rare (Grimbacher et al. 1999a, b). In contrast IgA deficiency is not a single gene disorder and shows some MHC involvement (Vorechovsky et al. 1999). With a prevalence of 1 in 600, such disorders are not likely to be major contributors to disease patterns, but unusual

clinical manifestations of an infectious disease may be associated with them. Of more relevance to this chapter are the studies of common variants that control Ig levels. Total IgE levels are the best studied, as a result of involvement in asthma and atopy, and are considered together with the genes on 5q31–q33. A genome scan has been carried out implicating a region of chromosome 13 in control of total IgA levels (Wiltshire et al. 1998).

Aside from investigation of Ig levels, there have been few attempts to examine common genetic control of the immune system, independently of infection. Genetics has a major influence on the variation in peripheral T-cell subset numbers: Hall et al. (2000) reported heritabilities of 65 percent for CD4:CD8 T-cell ratio, about 50 percent for absolute lymphocyte, $CD3^+$ and $CD4^+$, counts, and 56 percent for $CD8^+$ numbers. The human NK-cell repertoire is influenced by variation in *KIR* (coding for killer cell Ig-like receptor) and HLA class I (Shilling et al. 2002). Murine studies have shown that the IgE-suppressive activity of IFN-γ is polymorphic and controlled by a gene outside *H-2* (Matsushita and Katz 1992). Use of an infection-free phenotype, IL-12 responsiveness, and therefore subsequent ability to mount a T-helper 1 (Th1) or T-helper-2 (Th2) response implicated the Th2 gene cluster (Gorham et al. 1996). Examination of the effects of genetic variation on protein production, especially cytokine production, has proved fraught with problems (Nieters et al. 2001). This contrasts with some success in tying in polymorphisms with other immune response phenotypes, and is in part the result of problems associated with laboratory techniques, e.g. use of bulk cultures (Zipp et al. 2001). Proliferative responses to crude and defined antigens such as vaccine candidates, and skin test responsiveness, have been the subjects of limited study in the recent past. As anticipated there is some influence of HLA, but non-MHC genes are also implicated (Jepson et al. 1997a; Blackwell et al. 1999).

COMMONLY INVESTIGATED GENES

Commonly investigated genes for susceptibility/resistance to particular pathogens contribute to both innate and acquired immunity. The genes described below are those most widely investigated and/or genes localized to clusters of immune response genes, which have often arisen through gene duplication.

HLA class I and class II

Classic HLA molecules are particularly relevant to genetic studies through their role in antigen presentation, and consequent influence on responsiveness to infection and immunization. The human MHC, on chromosome 6p21.31, is arguably the most interesting region in immunogenetics because this is the most polymorphic

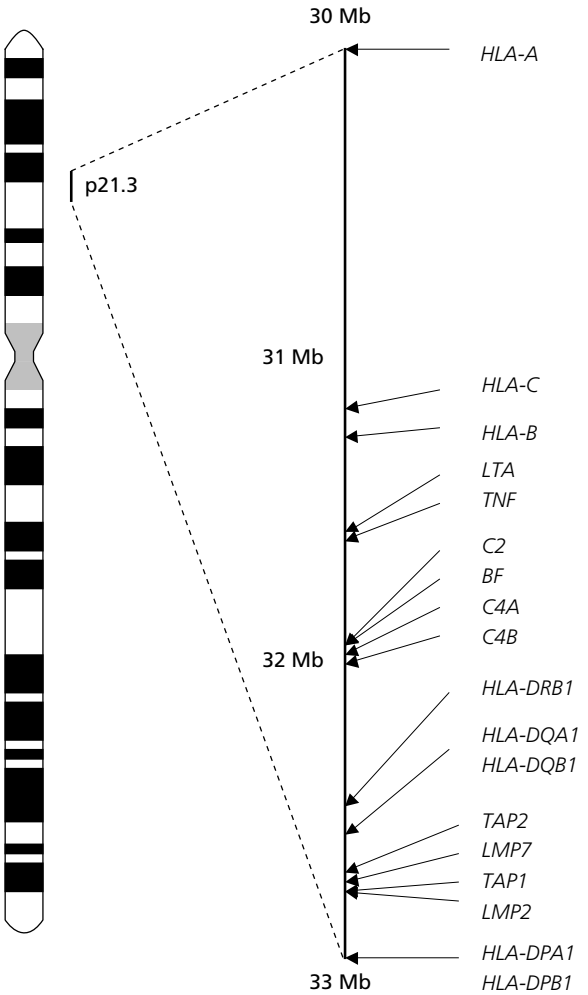

Figure 1 *Chromosome 6: the MHC*

region of the genome, some genes having over 200 allelic variants (Figure 1). This multiple allelic diversity contrasts with the mechanisms for generation of diversity in Ig and T-cell receptor molecules, where single proteins are produced from several recombined gene segments. Almost all early immunogenetic studies concerned HLA, and analytically HLA provided the first group of highly polymorphic markers. HLA molecular structure, complexity, and allelic variation are well described (Marsh et al. 2000).

HLA class I was originally investigated genetically through its impact on transplantation, although class II molecules also have significant impact on graft rejection. Typically HLA class I was typed by serological methods, and HLA class II was typed by the mixed lymphocyte reaction. Nowadays, the vast majority of HLA typing is done by polymerase chain reaction (PCR) using sequence-specific primer or sequence-specific oligonucleotide methodology. The improved resolution of DNA-based typing has contributed to the subdivision of previously described HLA alleles, e.g. *HLA-DR2* comprises *HLA-DRB1*15* and *HLA-DRB1*16*, which

complicates comparisons across studies. Peptide-binding specificities of alleles have been described. In 1999, ahead of publication of the human genome sequence, a complete sequence and gene map of a human MHC were reported (MHC Sequencing Consortium 1999). At this time there were 224 identified loci, of which it was predicted that 128 were expressed, about half of which had immune function. Many of these genes were identified as a result of the sequencing and many remain of unknown function. As the entire region contains over 200 genes in 3–4 Mb of DNA, the study and use of haplotypes and linkage disequilibrium are very important. HLA associations have been reported for the disease per se, position on the clinical spectra of disease, and ability to respond to crude and defined antigens; both qualitative and quantitative traits. For many infectious diseases, it remains the only region investigated to date.

HLA study design typically uses a case–control approach. Results are expressed as a relative risk of disease when carrying a particular allele. However, there were also early investigations of haplotype sharing among affected siblings, akin to current sib-pair analysis, which tackled the variable penetrance associated with susceptibility genes for complex disease. For the first and best-known HLA association, although more than 90 percent of patients with ankylosing spondylitis have *HLA-B27*, only a small percentage of individuals with *HLA-B27* will get clinical disease. In this way many early disease associations were reported, the most striking being for autoimmune disease. Many such conditions may have infectious triggers, or are more directly linked to known pathogens, such as rheumatoid and reactive arthritis, inflammatory diseases such as Crohn's disease and inflammatory bowel disease, and periodontal disease. HLA associations sometimes differ from other genetic associations because, as a result of the role of the HLA molecules in antigen presentation, a single copy of a particular allele suffices. HLA control of responses to particular antigens is best characterized for the immediate hypersensitivity response to allergens. The influence of HLA on specific IgE responsiveness to a wide variety of allergens has been known for many years, e.g. there are a number of MHC II-restricted epitopes in *Dermatophagoides pteronyssinus* allergen 1 (Higgins et al. 1994) and allergen 2 (Verhoef et al. 1993). However, although there is some evidence for HLA influence on *Der p*-specific IgE responsiveness, other loci are also involved, and genome scanning has implicated several loci (Hizawa et al. 1998a, b).

Although common haplotypes are known to occur, the HLA region is large enough for recombination to be seen and linkage disequilibrium to be incomplete. Linkage disequilibrium mapping, combined with examination of peptide-binding specificities, have been required to ascertain a complete picture. Perhaps the best example is for type 1 diabetes mellitus where a strong *HLA-DR3/DR4* association was known to occur. *HLA-DR3/DR4* alleles were thought to be too common to be disease-susceptibility alleles. In fact these alleles are in linkage disequilibrium with alleles at *HLA-DQB1*, which is the disease locus. Pinpointing disease susceptibility-causing mutations remains a problem in such a complex region.

The MHC has short sequence motifs, which essentially remain unaltered over millions of years. The class I and II regions, unlike the class III region, have many pseudogenes, possibly giving rise to new alleles via gene conversion. Class I and II arose by multiple duplication events (Shiina et al. 1999; Beck and Trowsdale 2000) and further duplication has resulted in differing copy number among haplotypes, which in turn may diverge to new functions. Those for *HLA-DRB* are the best known. How is allelic diversity maintained? The extreme polymorphism observed is likely to be a result of susceptibility/resistance to infectious agents. An excess of heterozygotes has been observed, suggesting balancing selection (Apanius et al. 1997; Jeffrey and Bangham 2000). Two theories are heterozygote advantage, where possession of two different alleles is optimal, and frequency-dependent selection, where low-frequency alleles are an advantage against pathogen-evasion strategies. One possible mechanism for the maintenance of diversity is through odor-mediated mate choice for mates of a different MHC type, hence maintaining heterozygosity. Selection may also promote different combinations of alleles or haplotypes. However, linkage disequilibrium and conservation of haplotypes will be influenced by clustered hot spots of recombination within the MHC (Jeffreys et al. 2001).

Class III genes – *TNF/LTA*

The class III region is the most diverse and gene-dense region, and may be the oldest because the origins of the MHC precede adaptive immunity.

For autoimmune, and later infectious diseases susceptibility, the most investigated cytokine genes are those coding for the macrophage proinflammatory cytokines tumor necrosis factor α (TNF-α) and IL-1. The gene for TNF-α (*TNF*) lies in the class III region between the gene *LTA* coding for lymphotoxin-α (also known as TNF-β) and *LTB* (Figure 1). This region is sometimes referred to as the class IV region. There are several polymorphisms in the *TNF* promoter, the best known of which is TNF_{-308}, alleles at which are often simply referred to as *TNF*1* and *TNF*2* (Knight and Kwiatkowski 1999; Ruuls and Sedgwick 1999). There is some confusion in the early literature because the first observed polymorphism, an *NcoI* restriction fragment length polymorphism (RFLP), was assumed to lie within *TNF*, and production of TNF-α appeared to relate to allelic variants. This polymorphism turned out to be in

the first intron of *LTA* (Messer et al. 1991): the then described *TNFB*1* resulted in an asparagine at amino acid position 26, whereas *TNFB*2* resulted in a threonine. This variant was reported by Messer et al. (1991) to determine TNF-β rather than TNF-α production. Although TNF_{-308} has been the focus of attention, the *LTA NcoI* RFLP has also been employed as a result of more informative allele frequencies. There is linkage disequilibrium reported between these two polymorphisms in a number of populations: *TNF*1/LTA*1* and *TNF*2/LTA*2* being more common than expected by random assortment.

Many early class I and II associations reported for disease susceptibility could be caused by linkage disequilibrium between these loci and those of the class III region, such as *TNF* and *LTA* (Jacob et al. 1990), e.g. the uncommon allele TNF_{-308}*2, which is often correlated with disease, shows very strong association with *HLA-A1*, *HLA-B8*, and *HLA-DR3* alleles (Wilson et al. 1993). Dissecting genetic effects in the region remains a problem. There have been numerous attempts to correlate particular alleles with function (e.g. Skoog et al. 1999). Many of the problems have related to study design, and the ability to demonstrate stable interindividual differences in cytokine production is rare (Molvig et al. 1988; Louis and Franchimont 1998). Despite issues over methodology (Kroeger et al. 1999), and diverse results (Brinkman et al. 1996; Wilson et al. 1997), undoubtedly confounded by attempting to examine the effects of a single base change on varied haplotypic backgrounds, TNF_{-308}*2 often shows higher production of TNF-α than TNF_{-308}*1 (Hajeer and Hutchinson 2001). TNF-α binds to two receptors TNF-R1 and TNF-R2, coded for elsewhere in the genome, both of which can be cleaved to release soluble receptors. The receptor genes have received less attention than the cytokine genes themselves, which is perhaps surprising in view of their role in the apoptotic pathway. Other class III genes include several coding for complement components.

The *IL1* gene cluster

The *IL1* gene cluster on chromosome 2q13 comprises *IL1A*, *IL1B*, and *IL1RN*, coding for IL-1α, IL-1β, and the IL-1 receptor antagonist, respectively (Figure 2). About 200 kb separates *IL1B* and *IL1RN* (Nicklin et al. 1994). A number of base change, microsatellite, and variable number tandem repeat (VNTR) polymorphisms have been identified in this region (Nothwang et al. 1997). It has been speculated, and occasionally demonstrated, that polymorphisms in each of these three genes may be functional, i.e. influence cytokine production (Pociot et al. 1992; Bailly et al. 1993; Danis et al. 1995). Such studies are difficult with a family of genes that are regulated at transcriptional, translational, and post-translational levels (Arend et al. 1998). The *IL1* gene cluster does show linkage disequilibrium (Cox et al. 1998), e.g. the $IL1B_{-511}$*2/$IL1RNV_{NTR}$*2 haplotype has been observed to be more common than anticipated by random assortment. These two alleles are thought to produce high levels of IL-1β and IL-1RA respectively. Although findings with this gene cluster are not so striking as those for the HLA class III region, *IL1* genes seem to be very important for control of certain infections, e.g. *IL1RN* in susceptibility to *Listeria monocytogenes* (Hirsch et al. 1996).

Some of the genes coding for the family of IL-1 receptors are also to be found on the long arm of chromosome 2, proximal to *IL1A*, *IL1B*, and *IL1RN* (Dale and

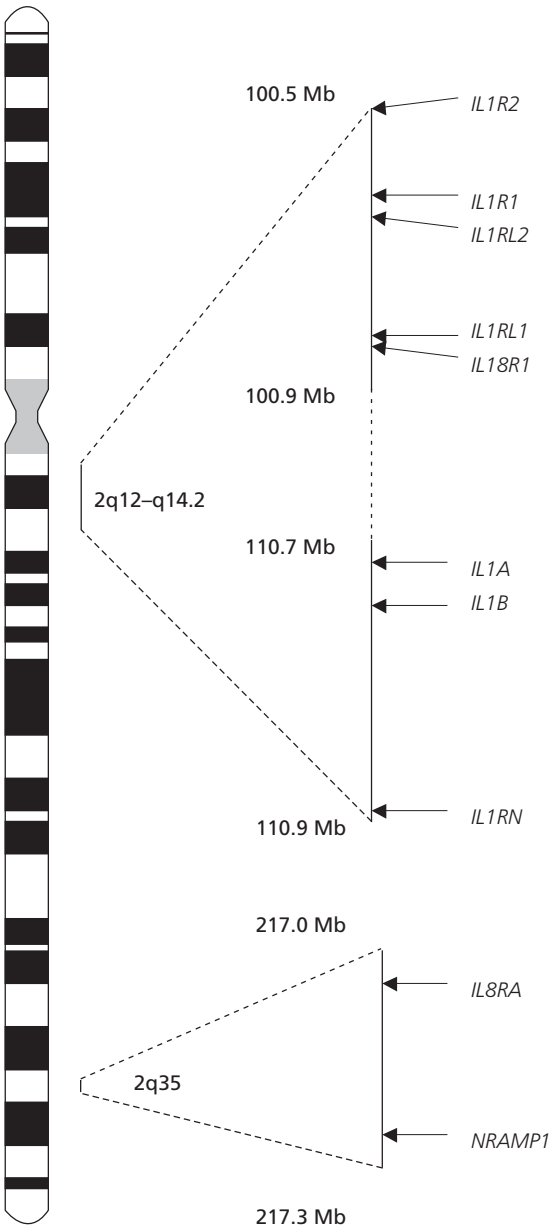

Figure 2 *Chromosome 2: the* IL1 *gene cluster and* NRAMP1.

Nicklin 1999). The most investigated are *IL1R1* and *IL1R2*. Another gene, *IL1RL1*, codes for the IL-1 receptor-related protein 1, which is a component of the IL-18 receptor. These genes are part of the larger IL-1 receptor/Toll-like receptor superfamily and additional members are still being described (O'Neill and Dinarello 2000). The proteins have three extracellular Ig-like domains. The soluble part of the type 1 IL-1 receptor has been crystallized together with the IL-1RA (Schreuder and Tardif 1997). As for *TNF*, the receptor genes have received less attention than the cytokine genes themselves, despite early indications that genetic variation of Toll-like receptor 4 may influence risk of gram-negative infections (Agnese et al. 2002). There are polymorphisms available for study, e.g. in the promoter of *IL1R1* (Bergholdt et al. 2000), although association studies with autoimmune conditions have been largely unrewarding. The IL-1 cytokines and receptors necessitate dissection of sometimes small genetic effects in a network of complex regulation and overlapping specificities.

SLC11A1 (*NRAMP1*, *Lsh/Ity/Bcg*)

SLC11A1, otherwise known as *NRAMP1*, is the best example of a locus that was originally investigated in the context of susceptibility to pathogens, rather than for its role in coding for an immune response protein (Figure 2). A number of inbred mouse strains have different susceptibilities to the intracellular macrophage pathogens *Salmonella typhimurium*, *Leishmania donovani*, and *Mycobacterium* spp. This genetic effect is remarkable because there is a clear dichotomy between resistant and susceptible strains, apparently under single gene control, with susceptibility proving recessive. Although the genes were named as *Ity*, *Lsh*, and *Bcg* respectively, following the cloning of *Nramp1* (natural resistance-associated macrophage protein) in 1993 by Vidal et al., it was proven, using a gene knockout and transfection, that the resistance to these intracellular macrophage pathogens was controlled by a single locus (Barton et al. 1995; Vidal et al. 1995). The human gene was named *NRAMP1*, now renamed *SLC11A1*, and lies on chromosome 2q35 near to *IL8R*. *Nramp1* has pleiotropic effects on macrophage function. The murine-resistant allele upregulates production of TNF-α and IL-1 and expression of MHC class II, and hence antigen-presenting capability. *Nramp1* codes for an integral membrane protein, with homology to transporters, and susceptibility is determined by a single nonconservative glycine/asparagine amino acid substitution (Vidal et al. 1993). Although the structure suggests a transport function, and despite identification of *Nramp1* as part of a family of transporter molecules (Cellier et al. 1995), the precise function has proved elusive. Subsequently localized to the late endosomal and lysosomal compartments, the protein is now thought to be an iron transporter (Blackwell and Searle 1999). The murine polymorphism has not been observed in human populations, highlighting potential problems of generalizing across species. However, cloning of the human homolog has been accompanied by identification of a number of other coding and noncoding polymorphisms (Cellier et al. 1994; Blackwell et al. 1995; Liu et al. 1995). One of these, a dinucleotide repeat in the human promoter, has been associated with functional differences in allelic expression (Searle and Blackwell 1998). There have been numerous attempts to demonstrate a clear role for *NRAMP1* in susceptibility to pathogens (Skamene et al. 1998, described below) and fewer studies examining its role in autoimmunity (Shaw et al. 1996; Blackwell and Searle 1999). One allele of the promoter polymorphism shows some association with autoimmune disease susceptibility and another allele with infectious disease susceptibility. However, findings are weak, relative to the murine system. This gene is being examined in other relevant species such as reservoir hosts (Altet et al. 2002).

Mannose-binding lectin and complement genes

Genes for classical, alternative, and membrane attack complex components are distributed throughout the genome. However, they occur in gene clusters, and there is substantial evidence of gene duplication and duplication of particular exons, e.g. those responsible for thioester bond formation, which enable key complement components to attach to the cell surface (Campbell et al. 1988; Schneider and Wurzner 1999). The genes *C2*, *C4A*, and *C4B*, and the gene coding for factor B, lie within the class III region of the MHC (see Figure 1). A variety of complement deficiency disorders is known, under single gene control. Unlike many 'single gene disorders', heterozygotes are relatively common, particularly for C2 deficiency: 1–1.5 percent of Caucasians have a *C2* null gene (Colten 1992). As mentioned above, complement deficiencies are associated with the autoimmune disorder systemic lupus erythematosus and infection with pyogenic bacteria (Walport 1993). Of the complement genes that have been investigated, predominantly those in the classical pathway, some, but not all, show polymorphic coding variation (Schneider and Wurzner 1999). As complement receptors, particularly those for C3, can act as receptors for invading microorganisms, and have a significant impact on infections such as HIV-1, it is to be expected that variation in the genes could impact on disease susceptibility (Fearon and Locksley 1996; Speth et al. 1997). However, despite a long history of research into variation in the complement system, these genes remain relatively poorly investigated with respect to infectious disease. There is also strong linkage disequilibrium between complement genes, especially

those in the class III region, hence, as for *TNF/LTA* and HLA class II genes, it is difficult to dissect genetic effects. Studies are rarely large enough to establish more than preliminary associations, and reported associations may merely reflect linkage disequilibrium with another nearby gene.
